USACE	U.S. Army Corps of Engineers, Los Angeles District

1.0 INTRODUCTION AND OBJECTIVES

The U.S. Army Corps of Engineers, Los Angeles District (USACE) is responsible for maintaining safe navigation for Southern California harbors, including the entrance to Marina del Rey Harbor and the federal channel leading to the Los Angeles River Estuary (LARE) through regular maintenance dredging. The USACE also manages routine maintenance dredging efforts for the federal navigational channels leading to the Port of Los Angeles (POLA), Port of Long Beach (POLB), Channel Islands Harbor, and Port Hueneme.

Portions, or all, of the material typically dredged from some of these locations contain chemical concentrations above federal numerical and aquatic toxicity screening values, rendering them unsuitable for unconfined, open ocean disposal or beach nourishment. Subsequently, dredging at these sites is hampered by a lack of readily available disposal options for the contaminated dredged material. Lack of suitable contaminated sediment disposal options often results in higher project costs and significant delays for both the USACE and the local sponsors (ports, counties, and cities within the Los Angeles Region).

There are currently two regional management documents that describe the recommended dredge material handling and disposal practices for contaminated sediments generated within the Los Angeles Region: They are (1) the recently completed *Los Angeles Contaminated Sediments Task Force (CSTF) Long-Term Management Strategy*, and (2) *Los Angeles Regional Dredged Material Management Plan (DMMP) Feasibility Study (FS)*, which is currently in preparation. The USACE, Los Angeles District, is an active participant and one of the lead agencies for the Los Angeles Region CSTF study and the lead agency for the preparation of the Los Angeles Region DMMP. Both studies focus on management issues related to contaminated sediments from dredging, and both studies include a recommendation for the development of one or more regional treatment facilities where contaminated sediments can be treated and processed into some form of beneficial reuse products.

Termed a STAR (Storage, Treatment, and Reuse) site by the CSTF members, this approach has been implemented elsewhere in the U.S. (New Jersey) and internationally (Hamburg, Germany) as a means of economically treating contaminated sediments. The concept is to create a centrally located facility where dredge materials can be transported to and subjected to one or

more treatment techniques in an effort to produce re-useable product(s) instead of simply relying on upland landfill or offshore ocean disposal alternatives.

Historically, sediment treatment is rarely used for maintenance or capital improvement dredging projects, except in the case of very large remediation efforts, because of the high set-up costs associated with the various technologies and difficulties locating suitable beneficial reuse opportunities. The concept of a STAR facility is to minimize project specific mobilization costs by building a permanent facility to handle multiple projects, thus spreading out the development costs over the life of the facility and making sediment treatment a more cost-effective alternative.

The overall goal of the current study is to conduct an opportunities and constraints analysis of available upland treatment technologies for potential use with contaminated sediments in the region, and prepare preliminary (conceptual) design drawings for siting and constructing a “STAR” treatment facility to manage contaminated, fine-grained, sediments in a cost-competitive and environmentally protective manner within the Los Angeles Region. Specific study objectives include the following:

- Identify potential treatment and disposal alternatives for use either singly or in a series within a regional treatment facility (summarized from U.S. Environmental Protection Agency [EPA] and U.S. Army Corps of Engineers [Corps] sediment treatment documents);
- Evaluate each alternative to determine its potential for effectiveness within Southern California and meet federal and state regulations, and select feasible alternatives for further evaluation;
- Develop preliminary (conceptual) design specifications for constructing a treatment facility, including options for siting the facility such as land-based or barge-based systems, facility space requirements, process rates, and costs for each of the final alternatives;
- Design and implement bench and field scale testing studies to evaluate the potential for separating contaminated sediments using a hydro-cyclone or similar mechanical separation device; and
- Using the results achieved during the laboratory and field bench scale studies, develop conceptual design drawings for potential full-scale treatment facilities.

Because the information developed for this study can also benefit the Los Angeles Regional DMMP, portions or all of some tasks have been funded by the DMMP (e.g., Hydrocyclone Field Pilot Study) and appear under this program as well as certain DMMP deliverables (e.g., Technical Memorandum for developing regional treatment facility). In addition, portions of this report may be used by members of the Los Angeles Contaminated Sediments Task Force to support their ongoing efforts to select study locations for implementing a regional treatment facility.

The remainder of this document addresses each of these objectives. Section 2 presents a brief description of the study area for which the USACE is responsible, summarizing the nature and extent of the dredge material typically encountered and for which this document would likely apply. Section 3 provides background information on regional sediment characterization. Sections 4 and 5 provide a review of available treatment technologies extracted, almost *verbatim*, from EPA's Assessment and Remediation of Contaminated Sediments (ARCS) Remediation Guidance Document. This information is provided because it offers an excellent summary of the available treatment technologies that could be considered for the development of regional treatment facility, and provides a convenient introduction to the alternatives evaluation subsequently conducted in Section 6. Where appropriate, site-specific information pertaining to an alternatives past use within the study area has been added. Section 7 examines STAR facility siting requirements and operational considerations for developing a regional treatment facility in the Los Angeles Basin. Lastly, Section 8 provides conclusions and recommendations for future study.

2.0 STUDY AREA

The study area for which this dredge material treatment technology evaluation is focused includes the coastal waters between Ventura and Orange Counties. This area extends, generally, from Port Hueneme to the north, down past Santa Monica Bay and San Pedro, all the way to Newport Beach. Specific federal dredge material management areas within the study area include Port Hueneme, Channel Island Harbor, Marina del Rey and the mouth of Ballona Creek, King Harbor, the POLA and POLB, the mouth of the LARE, Alamitos Bay (Figure 2-1), and Newport Bay. Each of these areas has a unique geographic setting, as described below and some frequently require the management of contaminated sediments associated with routine channel maintenance. Problem areas include Port Hueneme, Marina del Rey, LARE, and Newport Bay, and are the focus for this study.

2.1 Port Hueneme

The Port of Hueneme, located in Ventura County, is the only deep water harbor between Los Angeles and the San Francisco Bay area and is the U.S. Port of Entry for California's central coast region (Figure 2-2). It serves international businesses and ocean carriers from the Pacific Rim and Europe. The Port of Hueneme ranks among the top seaports in California for general cargo throughput. The niche markets that Hueneme serves include: the import and export of automobiles, fresh fruit and produce, and forest products. The Port of Hueneme is also the top seaport in the United States for citrus export and ranks among the top 10 ports in the country for automobile and banana imports. Its unique positioning near the Santa Barbara Channel has also made the Port of Hueneme the primary support facility for the offshore oil industry in California's central coast area. The USACE maintains a federal channel into Port Hueneme harbor, which is jointly shared by the U.S. Naval Base Ventura County.

Either as a result of past U.S. Naval or port operations in the harbor, or some yet unidentified source, the sediments located in Port Hueneme are contaminated with Dichlorodiphenyltrichloroethane (DDT), Polychlorinated Biphenyls (PCBs) and some Polycyclic Aromatic Hydrocarbons (PAHs). Bulk sediment concentrations have been detected at levels between low- and mid-range screening values and most have been determined not suitable for aquatic disposal. Physical characteristics of the material are dominated by high sand content and low organic carbon content. Additional details are provided in Section 3.

Figure 2-1
Upland Treatment Technologies Investigation Study Area

Figure 2-2
Port Hueneme

2.2 Santa Monica Bay

Santa Monica Bay is an open coastal embayment situated on the western coastline of Los Angeles County (the County). The bay is bounded on the west by the Santa Monica Basin in the Pacific Ocean, north by Point Dume, south by the Palos Verdes Peninsula and Redondo Submarine Canyon, and shoreward by the Los Angeles Coastal Plain to the east and Santa Monica Mountains to the north. Marina del Rey and King Harbor are major small craft harbors located on the mid, and southern coast of Santa Monica Bay. Ballona Creek enters Santa Monica Bay adjacent to the entrance channel of Marina del Rey. These three locations represent ongoing sources of sediment to this portion of the study area. The Santa Monica Bay and harbors system supports extensive commercial and recreational use including commercial and recreational boating and fishing, surfing, swimming, and beach recreational activities.

2.2.1 Marina del Rey

Formally dedicated in April 1965, Marina del Rey was constructed in the area formerly known as the Playa del Rey Estuary (Figure 2-3). In the past three decades, the harbor has become one of the largest man-made recreational boat harbors in the world with over 6,000 slips available for private boater's commercial fishing vessels, and Coast Guard vessels. To protect the harbor against wave damage during winter storms, a breakwater was constructed perpendicular to the mouth of the harbor in January of 1965. The Marina del Rey harbor is operated and maintained by the Los Angeles County Department of Beaches and Harbors. Navigation within the approach and entrance channels is maintained by USACE.

2.2.2 Ballona Creek

Originally a natural, meandering waterway draining runoff from the hills north of Hollywood and the West Los Angeles Basin, Ballona Creek was channelized and lined with concrete in 1935 by the USACE as a flood control measure and now discharges parallel to the entrance channel jetties of Marina del Rey (Figure 2-3). Much of Ballona Creek today is simply a large flood control channel, draining storm water runoff from a large, heavily urbanized area west and northwest of downtown Los Angeles.

Figure 2-3
Marina del Rey and Ballona Creek

During winter storm events, significant quantities of sediment are transported down Ballona Creek, where they are trapped behind the breakwater constructed to protect the Marina del Rey harbor instead of flowing into Santa Monica Bay.

Operation and maintenance of the flood control channel are partitioned between the USACE and Los Angeles County Department of Public Works (LACDPW). USACE has jurisdiction between Washington Boulevard to La Salle Avenue and Vista del Mar to the Pacific Ocean and LACDPW has jurisdiction over the remainder of the channel. In the portion under its jurisdiction, USACE is responsible for maintenance activities required to maintain the function and structural performance of the flood control channel. Other maintenance activities involving aesthetics, water quality, and vector control are performed by LACDPW and Culver City. USACE also has the jurisdiction to review and approve proposed improvements or alterations to the Ballona Creek flood control channel to ensure there will not be any adverse effects of flood control channel functions. LACDPW may review and approve proposed improvements or alterations to the Ballona Creek flood control channel within the LACDPW jurisdiction reaches.

2.2.3 King Harbor

Redondo Beach – King Harbor is a small craft harbor occupying approximately 60.7 hectares of land and water at the southern end of Santa Monica Bay. King Harbor is about 27.4 kilometers (km) southwest of the business center of the City of Los Angeles and about 11.3 km south of the Los Angeles Airport (Figure 2-4). It has been an active harbor since the early 1900s when it was a commercial port. After the POLA became fully operational, Redondo Beach – King Harbor became focused on pleasure craft and fishing boats. The harbor extends approximately 1,219 meters (m) along the coast and is roughly 610 m wide at the widest point.

The City of Redondo Beach is responsible for maintenance of the interior harbor that includes the three boat basins and the wave protection baffles at the entrances to Basins 1 and 2, built by the federal government. As part of its Operations and Maintenance Program, USACE is responsible for maintenance of the breakwaters.

Figure 2-4
Redondo Beach - King Harbor

2.3 San Pedro Bay

San Pedro Bay is an open coastal embayment situated on the southern coast of the County. The bay is bounded by Point Fermin on the west, San Pedro Basin on the southwest, Newport Submarine Canyon on the south, and the coastal plain from San Pedro to Newport Beach along the coast.

Originally a large tide flat and salt marsh, the area that was once called Bahia de los Fumos or the “Bay of Smokes” in 1542, later became known as San Pedro Bay. Around the turn of the century (1907) the POLA was created and a few years later in 1911, the POLB was created at the mouth of the Los Angeles River. An aerial view for the two Ports is shown in Figure 2-5. Port development grew rapidly and by 1912 the first section of the breakwater was constructed and the main shipping channel was dredged to a depth of 9 m to accommodate the largest vessels of that era. Sediment input into San Pedro Bay occurs via two main upland sources: the Dominguez Channel and the Los Angeles River. Although not as significant, some sediment transport also occurs into San Pedro Bay via coastal currents through the openings in the breakwater that shelters the bay.

The Dominguez Channel, previously known as the Dominguez Slough, drains an approximately 259 square kilometers (km²) watershed located in southern Los Angeles County. Like all of the other waterways in the Los Angeles Basin, most of the Dominguez Slough was channelized in the mid-1900s in an effort to provide flood protection to the County area.

2.3.1 Los Angeles River Estuary

The LARE is located at the mouth of the Los Angeles River in Long Beach (Figure 2-6). Queensway Marina, Rainbow Harbor/Marina, and Shoreline Marina are located in the LARE and operated by the City of Long Beach. These facilities serve primarily recreational boating and cruise ships to Catalina Island.

Figure 2-5
San Pedro Bay,
Port of Los Angeles, Port of Long Beach, and Alamos Bay

Figure 2-6
Los Angeles River Estuary

The Los Angeles River Watershed covers a land area of over 2,135 km² (834 square miles [mi²]) from the eastern portions of Santa Monica Mountains, and Simi Hills, and Santa Susana Mountains to the San Gabriel Mountains in the west. The watershed encompasses and is shaped by the path of the Los Angeles River, which flows from its headwaters in the mountains eastward to the northern corner of Griffith Park where the channel turns southward through the Glendale Narrows before it flows across the coastal plain and into San Pedro Bay near Long Beach. The Los Angeles River Watershed has diverse patterns of land use. The upper portion of the watershed, 920 km² (approximately 360 mi²), is covered by forest or open space, while the remaining watershed, 1,215 km² (approximate 474 mi²), is highly developed with commercial, industrial, or residential uses.

There are eight major tributaries to the Los Angeles River as it flows from its headwaters to the Pacific Ocean. The major tributaries of the Los Angeles River include Burbank Western Channel, Pacoima Wash, Tujunga Wash, and Verdugo Wash in the San Fernando Valley; and the Arroyo Seco, Compton Creek, and Rio Hondo south of the Glendale Narrows. The Los Angeles River Watershed has 22 water bodies within its boundaries including Devil Gates Dam, Hansen Basin, Lopez Dam, Pacoima Dam, and Sepulveda Basin. In addition, there are a number of spreading grounds in the watershed including sites at Dominguez Gap, the Headworks, Hansen Dam, Lopez Dam, and Pacoima Dam. The Rio Hondo, a tributary to the Los Angeles River is hydraulically connected to the San Gabriel River through the Whittier Narrows Reservoir during large storm events.

The Los Angeles River, which once flowed freely over the coastal plain, was channelized between 1914 and 1970 to control the runoff and reduce the impacts of major flood events in the Los Angeles Region. Today, the Los Angeles River is lined on 77 km (47.9 miles [mi]) of its 82 km (51 mi) length. There are three stretches where the channel bottom is not lined with concrete reinforcement. They are:

- Within the Sepulveda Flood Control Basin
- Through the Glendale Narrows
- South of Willow Street in Long Beach

The Los Angeles River, along most of its course, had intermittent flow during much of the year prior to channelization. In addition, many of its tributaries did not reach the river except during storm events. The current flow in the river is effluent dominated with approximately 80 percent of its flow originating at dischargers and the remaining flow coming from storm drain runoff and groundwater reaching the surface (LACDPW 2003).

2.4 Alamitos Bay

Alamitos Bay is located just southeast of the Los Angeles/Long Beach Harbor Complex in Naples/Belmont Shores (Figure 2-5). The Alamitos Bay Marina was created with the dredging of marshland in 1949 and opened in the mid-1950s. Today, the marina serves primarily recreation boats and is surrounded by residential and commercial areas. Located within Alamitos Bay Marina are the island of Naples, Marine Stadium that was built for the 1932 Olympic rowing competition, and the Los Cerritos Channel. Recreational activities include sailing, motor boating, canoeing, kayaking, board sailing, wind surfing, water skiing, and rowing.

The Alamitos Bay Marina entrance is defined by two jetties located adjacent to the San Gabriel River mouth. The City of Long Beach Department of Parks, Recreation, and Marine is responsible for maintaining the recreational navigation of the harbor entrance and marina and conducts regular maintenance dredging within the entrance channel.

2.5 Newport Bay

Newport Bay in the City of Newport Beach, Orange County, California, is located on the Central Orange County coast, roughly 40 mi southeast of Los Angeles, and 70 mi northwest of San Diego (Figure 2-7). Newport Bay is a combination of two distinct bodies of water—Lower Newport Bay and Upper Newport Bay. Lower Newport Bay, referred to as the outer harbor, was formerly a coastal lagoon. It is 4 miles long and is oriented parallel to the coastline. This lagoon was formed between 1824 and 1862 as a result of sand deposition from the Santa Ana River. Upper Newport Bay is geologically much older than the Lower Bay, and it is essentially a submerged river valley formed by a precursor to the Santa Ana River. Today, it comprises a marine salt marsh system. The lower portion of the Upper Bay is heavily urbanized, and supports adjacent housing development, recreational marinas, boat launch ramp facilities, and other commercial uses.

Figure 2-7
Newport Bay

Newport Bay and the adjoining coastal areas of Newport Beach and Corona del Mar present significant recreational opportunities on a local and regional level. The area serves as a major vacation destination within Southern California and the Southwest. The Lower Bay, having an open water area of about 600 acres, offers recreational opportunities to a wide range of boating enthusiasts; from single-person rowboats to large sailing and motor vessels that are capable of trans-ocean navigation. The local beach front communities also support water recreational services, with tourism as one of the most important land use activities in the regional area. These areas offer opportunities for bicycling, roller skating, rollerblading, walking, as well as volleyball, picnicking, sunbathing, swimming, diving, and surfing.

To maintain federally authorized channel depths of -6.1 m (-20 feet [ft]) mean lower low water (MLLW), the USACE has been instrumental in the removal of sediment from the lower portion of the Upper Bay Channel to the Main Channel junction. Dredge material from upper and lower Newport Bay typically contains elevated concentrations of metals and pesticides resulting from urban runoff in the San Diego Creek watershed. Recent dredge material characterizations in the bay show DDT levels above ecological screening values, eliminating ocean disposal as a viable alternatives for dredge material management.

3.0 REGIONAL SEDIMENT CHARACTERIZATION

This section provides an overview of sediment physical and chemical parameters typical of dredge material within the Los Angeles Region study area. Data are summarized for Port Hueneme, POLA, POLB, Santa Monica Bay, San Pedro Bay, LARE, and Newport Bay.

3.1 Sediment Data Sources

The primary source of data used to prepare this summary is the CSTF database constructed specifically for use in developing a Contaminated Sediments Management Strategy document and for the USACE DMMP FS. The primary sources of data used to create the database include work provided by the POLA, POLB, City of Long Beach, the County, USACE, National Oceanic Atmospheric Association (NOAA), and Southern California Coastal Water Research Project (SCCWRP). The database is located on the SCCWRP website at www.sccwrp.org.

The data contained within the CSTF database includes all sediment characterization information available for the region where the material was considered for aquatic or upland disposal. Other data (e.g., grain size, density, etc.) exists for sediment collected within portions of San Pedro Bay, but this information was not included in the current evaluation because it was collected for use in a specific fill project and was never considered for any other form of disposal. In other words, the material would not have been subjected to the recommendations provided in this plan. For example, portions of the Los Angeles Harbor channel deepening project were directly tied to the construction of the Pier 400 terminal within the POLA. The sediments were characterized for physical strength solely to determine fill site compatibility and the analyses did not include chemical measurements. As such, this information was excluded from the CSTF database and is not presented in this report.

Other sources of data that were used include the recently completed Los Angeles DMMP Pilot Studies (USACE 2002a), the Preliminary Draft Marina del Rey DMMP (Chambers Group 1998), and the Year 2000 Biological Survey of the POLA and POLB (MEC 2002).

3.2 Port Hueneme

USACE sediment management activities in Port Hueneme include maintaining the federal navigation channel into the harbor which is used jointly by the Oxnard Harbor District and

U.S. Navy (Naval Base Ventura County). The Corps has also recently conducted a Feasibility Study for deepening the authorized navigation depth of the federal channel which would require removing sediments that have tested high in contaminants during planning study sampling events. Available sediment characterization data includes sample results from these recent planning studies.

3.2.1 Physical Characterization and Distribution

3.2.1.1 Grain Size

Sediment grain size distribution for the Port of Hueneme is summarized in Table 3-1. Sand contents range from 2 percent to 99 percent with an average of 75.5 percent; silt contents range from 2 percent to 98 percent, with an average of 22.3 percent. Clay and gravel are rarely encountered in Port Hueneme dredged material, averaging 0.44 and 1.76 percent respectively.

Table 3-1
Summary of Sediment Physical Characteristics for Port Hueneme Dredged Sediments

Analyte	Units	Min	Max	Avg	Percent Detection	N
Sand	PCT	2	99	75.5	100	130

ND = non-detected

PCT = percent

3.2.2 Chemical Characteristics and Distribution

3.2.2.1 Inorganics

Port Hueneme sediment inorganic concentrations are summarized in Table 3-2.

Overall, inorganic concentrations are quite low with average values never exceeding the very conservative ER-L threshold screen. Only occasionally did maximum concentrations exceed ER-L values. Examples where the maximum values detected exceed the ER-L include cadmium, nickel, and silver. The maximum concentration for mercury exceeds the ER-M screening value.

Table 3-2
Summary of Sediment Inorganic Concentrations for Port Hueneme Dredged Sediments

Analyte	Units	Min	Max	Avg	Percent Detection	N	ER-L	ER-M
Arsenic	mg/kg	0.7	5.6	2.8	100	46	8.2	70

Zinc	mg/kg	3.1	84	34.3	100	46	150	410

ND = non-detected

3.2.2.2 Semi-Volatile Organics

Port Hueneme sediment semi-volatile organic concentrations (SVOA) are summarized in Table 3-3. As expected, concentrations vary by chemical and the range in concentrations for some compounds is quite large. Sediment screening values (e.g., ER-L, ER-M) do not exist for all the SVOA compounds tested.

Acenaphthylene, Anthracene, Fluorene, and Total PAHs had maximum concentrations that exceed ER-L values. Maximum concentrations that meet or exceed ER-M values include Benzo(a)anthracene, Benzo(a)pyrene, Chrysene, Fluoranthene, and Pyrene.

Table 3-3
Summary of Sediment SVOA Concentrations for Port Hueneme Dredged Sediments

Analyte	Units	Min	Max	Avg	Percent Detection	N	ER-L	ER-M
2,4-Dichlorophenol	µg/kg	ND	20	6.5	57	46	—	—

ND = non-detected

3.2.2.3 Pesticides/PCBs

Port Hueneme sediment pesticide and PCB concentrations, as reported in the CSTF database, are summarized in Table 3-4. DDT, Total PCBs, Chlordane and Dieldrin are the only pesticides/PCBs that have ER-L and ER-M screening values. DDT has an average concentration that exceeds the ER-L value. Chlordane and Dieldrin have maximum concentrations that exceed the ER-L value. On a particular note, Total PCBs have a very high maximum concentration of 1300 µg/kg which exceeds the ER-M value (180).

Table 3-4
Summary of Sediment Pesticide/PCB Concentrations for Port Hueneme Dredged Sediments

3.3 Santa Monica Bay/Marina del Rey

Within Santa Monica Bay, USACE sediment management activities are limited to Marina del Rey, the mouth of Ballona Creek, and the jetty located at the mouth of King Harbor.

Sediment characterization data (other than bathymetry and grain size) is readily available

for Marina del Rey and Ballona Creek, but only one record exists for King Harbor. As such, the majority of the data presented in this section will be limited to the former two locations.

3.3.1 Physical Characterization and Distribution

3.3.1.1 Grain Size

Sediment grain size distribution in Marina del Rey/Ballona Creek sediments is summarized in Table 3-5. Sand content ranges from 51.2 percent to 97.9 percent with an average of 79.3 percent; silts range from less than 1 percent to almost 67 percent, with an average of 25.5 percent; and clays range from less than 1 percent to 59.5 percent with an average of 17 percent. Gravel is rarely encountered in Marina del Rey dredged material, averaging only 2.5 percent. A typical grain size distribution for the entrance of Marina del Rey is shown in Figure 3-1.

Table 3-5
Los Angeles CSTF Database – Summary of Sediment Physical Characteristics for Marina del Rey Dredged Sediments

Analyte	Units	Min	Max	Avg	N
Sand	PCT	51.2	97.9	79.3	38

Percent Moisture	PCT	21.5	70	47.1	90

PCT = percent

3.3.2 Chemical Characteristics and Distribution

3.3.2.1 Inorganics

Marina del Rey sediment inorganic concentrations from the CSTF database are summarized in Table 3-6. Inorganics have concentrations ranging from just below the ER-L screening value to well above the ER-M screening value. Copper concentrations contained maximum values of almost two times the ER-M screening value. Arsenic, lead, mercury, and nickel all had maximum concentrations that exceed ER-M values.

Figure 3-1
Median Grain Size Distribution for Marina del Rey

Table 3-6
Los Angeles CSTF Database – Summary of Sediment Inorganic Concentrations for Marina del Rey Dredged Sediments

Zinc	mg/kg	13.9	647	220.1	100	191	150	410

ND = non-detected

3.3.2.2 Semi-Volatile Organics

Marina del Rey SVOA concentrations are summarized in Table 3-7. With the exception of 13 compounds (all the phenolic compounds, acenaphthylene, dimethyl phthalate, and naphthalene), all were detected in at least one of the samples tested. Excluding Fluorene, the minimum and maximum concentrations for semi-volatile organics sampled never exceed the ER-L and ER-M screening values.

3.3.2.3 Pesticides/PCBs

Marina del Rey sediment pesticide and PCB concentrations, as reported in the CSTF database, are summarized in Table 3-8. DDT, Chlordane, and Dieldrin are pesticides that may be of concern for dredging events at Marina Del Ray. DDT has maximum concentrations that exceed the ER-M. Chlordane and Dieldrin have average concentrations that exceed both the ER-L and ER-M screening values. Although Total PCB has a screening value for ER-L (22.7) and ER-M (180), they were not detected at Marina Del Ray.

ND = non-detected

Although no ER-L screening values exists for PCBs, elevated concentrations are reported for Marina del Rey sediments. Concentrations of Aroclor 1260, a common PCB congener, range from 10 µg/kg to 755 µg/kg. Other screening values for PCBs (e.g., PSDDA SLs) suggest concentrations as low as 130 µg/kg may cause aquatic impacts.

3.4 San Pedro Bay

Sediment management areas within San Pedro Bay include the POLA, POLB, and the shipping lanes, which connect the two with the outer harbor (i.e. outside of the federal breakwater). The majority of the sediment characterization data available for the ports has been separated into two categories (POLA and POLB), based on study sponsor. As such, the data are reported separately within this section.

3.4.1 Physical Characteristics and Distribution

3.4.1.1 Grain Size

A general survey of the San Pedro Harbor, conducted by MEC in 2000 (MEC 2002), shows a variable grain size distribution within San Pedro Bay, depending on the habitats sampled (Figure 3-2 and Table 3-9). As expected, the shallow water man-made mitigation areas in the Ports consistently contained the highest sand content while the back channel, dead-end reaches contained the highest silt/clay content. The following subsections summarize the available grain size and organic carbon data conducted specifically as part of various dredge characterization projects and contained in the CSTF database.

3.4.1.1.1 Port of Los Angeles

Sediment grain size distribution within the POLA is summarized in Table 3-10. Sand contents range from 2 percent to 99.4 percent with an average of 55.1 percent; silt contents range from 0 percent to 80 percent, with an average of 27.8 percent; and clay contents range from 0 percent to 45.4 percent with an average of 9.3 percent. Gravel contents are much lower, ranging from 0 percent to 46.9 percent and averaging 2.1 percent. Organic carbon contents for POLA dredge materials are reported ranging from 0.1 percent to 11 percent, and averaging 1.2 percent.

3.4.1.1.2 Port of Long Beach

Sediment grain size distribution within the POLB is summarized in Table 3-11. Sand contents range from 4.6 percent to 98.9 percent with an average of 44.4 percent; silt contents range from 0.9 percent to 77.1 percent, with an average of 37.4 percent; and clay contents range from 0.1 percent to 42.8 percent with an average of 15.7 percent. Gravel contents range from 0 percent to 20.7 percent, with an average of only 1.9 percent. Organic carbon contents for POLB dredge materials are reported ranging from 0 percent to 2.6 percent, and averaging 0.7 percent.

3.4.2 Chemical Characteristics and Distribution

3.4.2.1 Inorganics

3.4.2.1.1 Port of Los Angeles

POLA dredge material inorganic concentrations from the CSTF database are summarized in Table 3-12. Nine metals have maximum concentrations that exceed the ER-M values. Copper has maximum concentrations that are almost ten times the ER-M value; mercury has an average concentration that exceeds the screening values for ER-L and ER-M.

Table 3-12

3.4.2.1.2 Port of Long Beach

POLB dredge material inorganic concentrations from the CSTF database are summarized in Table 3-13. Copper, mercury, and lead have average concentrations that exceed the conservative ER-L value. About half of the inorganic compounds have concentrations that exceed the ER-M value.

Table 3-13

3.4.2.2 Semi-Volatile Organics

3.4.2.2.1 Port of Los Angeles

POLA sediment SVOA concentrations are summarized in Table 3-14. With the exception of 15 compounds (all of the phenolic compounds, dibenzofuran, dibutyl phthalate, and methoxychlor), all were detected in at least one of the samples tested. Eight semi-volatile organics have an average concentration that exceeds the ER-L value. Of particular note, Total PAHs have a maximum concentration that is five times the ER-M screening value.

3.4.2.2.2 Port of Long Beach

POLB SVOA concentrations are summarized in Table 3-15. Sediment screening values (e.g., ER-L, ER-M) do not exist for all the SVOA compounds tested. Acenaphthene has an average concentration that exceeds both the ER-L and ER-M screening values. Benzo(a)anthracene, Benzo(a)pyrene, Fluoranthene, and Fluorene have high maximum concentrations that exceed both the ER-L and ER-M screening values. Naphthalene has a maximum concentration that exceeds the ER-L screening value.

3.4.2.3 Pesticides/PCBs

3.4.2.3.1 Port of Los Angeles

POLA sediment pesticide and PCB concentrations, as reported in the CSTF database, are summarized in Table 3-16. Total PCBs have average concentrations that exceed both the ER-L and the ER-M screening values. DDT and Dieldrin both have maximum concentrations that exceed ER-L values.

3.4.2.3.2 Port of Long Beach

POLB sediment pesticide and PCB concentrations, as reported in the CSTF database, are summarized in Table 3-17. The average concentration for DDT is much greater than the screening value for ER-L. Dieldrin has a maximum concentration that is greater than the ER-L screening value. Total PCBs have data points that exceed both the ER-L (22.7) and ER-M (180) screening values. Concentrations of Aroclor 1260, a common PCB congener, range from 10 µg/kg to 1,200 µg/kg. Other screening values for PCBs (e.g., PSDDA SLs) suggest concentrations as low as 130 µg/kg may cause aquatic impacts.

3.5 Los Angeles River Estuary

As described in Section 2.3.1, sediment deposition in the LARE reflects the flow pattern of runoff from the Los Angeles River. The eastward bending of the estuary flow course has resulted in a deposition pattern where silt predominantly accretes along the northeastern shore (inner bend) of the estuary, whereas sand mostly accumulates on the opposite side

(outer bend) of the estuary. Lenses of relatively coarse sediment are present off Queensway Marina and at locations upstream.

Physical and chemical laboratory results from previous maintenance dredging characterization studies are available dating back to 1979. These results have been summarized and are presented in the following sections.

3.5.1 Physical Characterization and Distribution

3.5.1.1 Grain Size

Sediment grain size distribution in the LARE is summarized in Table 3-18. Sand contents range from 19 percent to 97 percent with an average of 61 percent; silt contents range from 1 percent to 45 percent, with an average of 24 percent; and clay contents range from 2 percent to 36 percent with an average of 13 percent. Gravel is rarely encountered in LARE dredged material, averaging only 1.4 percent.

Table 3-18
Los Angeles CSTF Database – Summary of Sediment Physical Characteristics for LARE Dredged Sediments

Analyte	Units	Min	Max	Avg	N
Sand	PCT	18.8	97	61.2	12
Silt	PCT	1.2	45.4	24.1	12
Clay	PCT	1.8	36.2	13.3	12

Total Sulfides	mg/kg	0.3	2,500	540.9	16
Dissolved sulfides	mg/kg	0.2	110	36.6	16

PCT = percent

3.5.1.2 Engineering Properties

With the exception of the recently completed DMMP Pilot Capping Study (USACE 2002a), little data exists on the geotechnical engineering properties of dredge materials from the LARE. Table 3-19 provides a summary of engineering properties from sediment cores collected throughout the dredge prism for the 2001 maintenance dredge event. Specific gravities for the material ranged from 2.3 to 2.7; dry densities from 655 kilograms per cubic meter (kg/m^3) to 1,920 kg/m^3 ; and void ratios from 0.39 to 2.05. The material had a liquid limit ranging from 30 to 55, and a plastic limit from 28 to 45. Moisture contents (reported as a percent) ranged from 14.6 for the areas with the highest sand content to 115.9 for areas with higher silt and clay contents.

Table 3-19 Summary of Geotechnical Engineering Parameters for Cores from the LARE

3.5.2 Chemical Characteristics and Distribution

3.5.2.1 Inorganics

LARE material inorganic concentrations from the CSTF database are summarized in Table 3-20. Inorganics have concentrations ranging from just below the ER-L and the ER-M screening values. Four inorganic compounds (lead, mercury, nickel, zinc) have an average concentration that exceeds the ER-L screening value.

Table 3-20
Los Angeles CSTF Database – Summary of Sediment Inorganic Concentrations for LARE Dredged Sediments

Analyte	Units	Min	Max	Avg	Percent Detection	N	ER-L	ER-M
Arsenic	mg/kg	0.7	12.3	5.0	100	17	8.2	70

Monobutyltin	µg/kg	ND	ND	ND	0	6	-	-

ND = non-detected

3.5.2.2 Semi-Volatile Organics

LARE sediment SVOA concentrations are summarized in Table 3-21. With the exception of three compounds (2-methylnaphthalene, dibenzofuran, and methoxychlor), all were detected in at least one of the samples tested. As expected, concentrations vary by chemical and the range in concentrations for some compounds is quite large. Sediment screening values (e.g., ER-L, ER-M) do not exist for all the SVOA compounds tested. With the exception of Acenaphthene and Fluorene, average concentrations for semi-volatile organics were below the ER-L screening value. Concentrations for Total PAHs never exceeded the ER-L and ER-M screening values.

Table 3-21
Los Angeles CSTF Database – Summary of Sediment SVOA Concentrations for LARE Dredged Sediments

Analyte	Units	Min	Max	Avg	Percent Detection	N	ER-L	ER-M
2-Methylnaphthalene	µg/kg	ND	ND	ND	0	9		
Acenaphthene	µg/kg	18	18	18	100	16	16	500

Total PAHs	µg/kg	1270	2,580	1,858	100	7	4,022	44,792

ND = non-detected

Other data, not yet contained in the CSTF database, suggests that some areas of the LARE contain much higher PAH concentrations, which easily exceeded the lower screening threshold values (Chambers Group 1998). As an example, a total PAH concentration of 17,473 µg/kg was recorded at one station in the LARE during a 1997 sampling event. The most recent sampling event (USACE 2002a), however, yielded results similar to those presented above.

3.5.2.3 Pesticides/PCBs

Despite the large potential upland source area to the LARE, pesticides and PCBs are rarely detected during sediment characterization studies for maintenance dredging (Table 3-22). DDT and its derivatives were detected and reported in the CSTF database, but at concentrations very close to the method detection limits. Arochlor 1248, 1254, and 1260 were also detected, but no ER-L type values exist for screening evaluation. The same is true for total dioxins, which were also detected.

3.6 Newport Bay

As described in Section 2, sediment deposition into Newport Bay is primarily from the San Diego Creek watershed entering into Upper Newport Bay. The USACE maintains a federal navigation channel inside the Bay to provide access to the U.S. Coast Guard and passenger ferry boats that operate from the Bay. Physical and chemical laboratory results from previous USACE maintenance dredging sediment characterizations are available and are presented in the following sections.

3.6.1 Physical Characterization and Distribution

3.6.1.1 Grain Size

Sediment grain size distribution in Newport Bay sediments is summarized in Table 3-23. Sand content ranges from 7.12 percent to 67.41 percent with an average of 37.02 percent; silts range from less than 13.07 percent to almost 38.83 percent, with an average of 26.87 percent; and clays range from less than 15.11 percent to 54.02 percent with an average of 34.61 percent. Gravel content ranges from 0.04 percent to 4.41 percent with an average of 1.48 percent.

Table 3-23
Summary of Sediment Physical Characteristics for Newport Bay Dredged Sediments

Analyte	Units	Min	Max	Avg	Percent Detection	N

PCT = percent

3.6.2 Chemical Characteristics and Distribution

3.6.2.1 Inorganics

Newport Bay sediment inorganic concentrations from the CSTF database are summarized in Table 3-24. About half of the samples tested had maximum concentrations that exceed the ER-L screening value. Mercury had maximum concentrations that were just above the ER-M screening value.

Table 3-24
Summary of Sediment Inorganic Concentrations for Newport Bay Dredged Sediments

Analyte	Units	Min	Max	Avg	Percent Detection	N	ER-L	ER-M
Arsenic	mg/kg	4.65	9.87	7.5	100	4	8.2	70

3.6.2.2 Semi-Volatile Organics

Newport Bay sediment SVOA concentrations are summarized in Table 3-25. With the exception of two compounds (Acenaphthylene and Napthalene), all were detected in at least one of the samples tested. Sediment screening values (e.g., ER-L, ER-M) do not exist for all the SVOA compounds tested. Minimum and maximum concentrations for semi-volatile organics tested were all below the ER-L and ER-M screening values.

Table 3-25

3.6.2.3 Pesticides/PCBs

Newport Bay sediment pesticide and PCB concentrations, as reported in the CSTF database, are summarized in Table 3-26. Total detectable DDT concentrations range from 29 to 161 µg/kg and average 74 µg/kg. This average is above the ER-M of 46.1 µg/kg which suggests that DDT is a chemical of concern for this area. It is important to note that the majority of the total DDT concentrations detected are actually DDE, a breakdown product of DDT. Other pesticides were detected, but no screening data are available for comparison.

Table 3-26

4.0 REVIEW OF AVAILABLE PRE-TREATMENT TECHNOLOGIES

Dredge material pre-treatment is a process where sediments are modified or conditioned prior to final treatment or disposal in an effort to maximize efficiency and/or reduce costs. In some cases, this pre-treatment step is all that is required or performed on the material to meet the target removal or remediation goals. As such, the term pre-treatment can be misleading in these instances because it ultimately becomes the final treatment step. Example pre-treatment processes include dewatering and particle separation.

The two primary reasons for pre-treating dredge material are (1) to condition the material so that it meets the requirements or physical characteristics of the final treatment or disposal components; and (2) to reduce the overall volume and/or weight of the sediments required for transport, treatment or disposal. Each is discussed briefly below.

Because most treatment technologies require a continuous feedstock of homogenous and physically uniform material to operate most efficiently, pre-treatment is an effective tool for achieving this goal. Dredge material solids content, particle size, and organic carbon content are some of the physical characteristics most commonly adjusted prior to final treatment. With the exception of adjusting sediment water content, pre-treatment is typically not required prior to dredge material disposal. Dewatering dredge material prior to disposal will reduce the weight of the material and, therefore, should result in reduced transportation and disposal costs. An added benefit to dewatering dredge materials prior to upland disposal is that it can eliminate potential water losses during transport which can reduce potential ancillary environmental impacts. Lastly, most upland landfills have a maximum moisture content that is allowed for material disposal (e.g., passing the paint filter test) so dewatering is typically a required component prior to implementing this alternative.

The second reason for pre-treating contaminated dredge materials is to reduce the overall volume and/or weight of the material prior to final treatment or disposal. Both treatment and disposal costs are heavily influenced by sediment volume and weight not only as a result of increased production volumes and longer operating schedules, but also from increased transportation and disposal tipping fees for the treated material. Physical separation technologies are available that can separate the typically clean, coarser-grained fractions of the sediment from the more contaminated fine-grained portion. Ideally this would result in

unrestricted disposal or beneficial reuse of a large percentage of the total dredge volume and, in turn, focuses the treatment effort on a much smaller residual sediment fraction. The use of physical particle separation as a sediment treatment alternative is discussed later in this document.

4.1 Dewatering Technologies

Typically, dewatering is employed to reduce the amount of water in sediments or residues to prepare the sediments for further treatment or disposal. The need for dewatering is determined by the water requirements or limitations of the treatment or disposal technologies and the solids content of the sediments following removal and transport. Within the Los Angeles Region, dewatering is commonly performed as a preliminary step for upland disposal or as a way to consolidate dredge materials used for nearshore fill projects (e.g., port terminal expansions).

Mechanically dredged sediments typically have solids contents comparable to that of *in situ* sediments (about 50% by weight for most fine-grained sediments). Hydraulically dredged sediments occur in slurry containing solids contents typically ranging from 10 to 20 percent. While some hydraulic dredge pumps are capable of higher solids contents (>20 percent), the average solids content in an extended dredging operation is rarely greater than 20 percent. To prepare dredged sediments for most treatment or disposal technologies, water must be removed and/or the solids content of the sediments must be made more uniform. Dewatering will be required for most sediment remedial alternatives that involve hydraulic dredging or transport. If the sediments are mechanically dredged and transported, the dewatering requirements may be greatly reduced or eliminated. Some technologies (e.g., cement-based stabilization) actually depend on the *in situ* water in the sediment to complete the chemical reactions that work to bind the contaminants thus eliminating the need to dewater prior to treatment.

Another function performed by dewatering is the reduction of the volume and weight of the sediments, which decreases the subsequent costs of handling, transport, and treatment and/or disposal of the solids. Dewatering will reduce the weight of a sediment load, but the effects of dewatering on the volume of a sediment load are more complex. When sediment slurry is dewatered, the removal of free water will directly reduce the volume of material

remaining in a nearly one-to-one relationship. Sediments that have been partially dewatered or mechanically dredged will lose additional water, but the volume will not always be reduced because the water driven from the voids between sediment particles is replaced by air. Some dewatering processes may even increase the bulk volume of the sediments and the water removed during the process may contain elevated chemical concentrations and require further treatment or disposal.

Three general types of dewatering technologies are discussed below:

- Passive dewatering
- Mechanical dewatering
- Active evaporating

4.1.1 Passive Dewatering

The term "passive dewatering" refers to those techniques that rely on natural evaporation and drainage to remove moisture. Drainage may occur by gravity or may be assisted (e.g., using vacuum pumps) and some mechanical movement of the sediments, such as the construction of trenches, may also be employed.

Passive dewatering of dredged material has traditionally been accomplished in confined disposal facilities (CDFs), which rely on primary settling, surface drainage, consolidation, and evaporation. Subsurface drainage and wick (vertical strip) drains have also been demonstrated or used at CDFs to promote dewatering and consolidation. These technologies require significant amounts of land and are most effective if the sediments can be spread out in thin layers or "lifts." Sediments can also be dewatered in temporary holding/rehandling facilities, tanks, and lagoons using the same design principles developed for CDFs.

Most CDFs constructed in the Los Angeles Basin have been accomplished by constructing dikes made of stone and granular material that remain permeable during construction. Lower lifts in the fill are accomplished by bottom-dumping dredge material within the perimeter of the dikes to form the base of the new land area. As material thickness in the fill increases and water depths decrease, the dike is closed off and the remainder of the material is either re-handled over the dikes or hydraulically

pumped into the fill area. Water drains through the permeable sections, and suspended sediments become entrapped by the dike material. As the CDF is filled above the water table, surface water is drained to the discharge point(s), which may include overflow weirs, filter cells, or pump control structures. Progressive trenching is a method that can be employed to aid the drainage of water in CDFs and hasten evaporative drying.

Once the CDF is completed, remaining water can be removed either through evaporation or subsurface drainage. The desiccation of dredged material by evaporative drying results in the formation of a crust at the sediment surface. This method of drying is a two-stage process. The first stage of drying occurs until all free-standing water has been decanted from the dredged material surface. The corresponding void ratio at this point is termed the initial void ratio (e_{00}) and has been determined to occur at a water content of approximately 2.5 times the Atterberg liquid limit of the material. The second stage of drying occurs until the material reaches a void ratio called the desiccation limit (e_{dl}). At this point, evaporation of any additional water from the dredged material will effectively cease. The e_{dl} corresponds to a water content of 1.2 times the Atterberg plastic limit (Corps 1987). The thickness of the crust and rate of evaporative drying and consolidation are dependent on local conditions and sediment properties, and can be estimated using the Primary Consolidation and Desiccation of Dredged Fill (PCDDF) module of the Automated Dredging and Disposal Alternatives Management System (ADDAMS) model (Schroeder and Palermo 1990).

To decrease dewatering times, a subsurface drainage system and/or leachate collection can also be implemented. One approach is the placement of perforated pipes under or around the perimeter of a CDF that drain into a series of sumps from which water is withdrawn. The pipes can be placed in a thin layer or trenches of drainage material, typically sand or gravel. The feasibility of subsurface drainage as a sediment dewatering technology may be limited where several layers of fine-grained sediments are to be disposed because they may clog the drainage materials.

Several variations of subsurface drainage systems can be used, including the gravity underdrain, vacuum-assisted underdrain, vacuum-assisted drying beds, and electro-osmosis. The gravity underdrain system provides free drainage at the base of the

dredged material by the gravity-induced downward flow of water. The vacuum-assisted underdrain is the same as the gravity-fed system, but uses an induced partial vacuum in the underdrainage layer. The latter system improves dewatering by 50 percent (Haliburton 1978), but requires considerable maintenance and supervision.

Wick drains or "wicks" are polymeric vertical strips that provide a conduit for upward transport of pore water, which is under pressure from the overlying weight of the material. By placing the vertical strips on 5-ft (1.5-m) centers to depths of 40 ft (12 m), both radial and vertical drainage are promoted. Wick drains can reduce consolidation time by a factor of 10 compared to natural consolidation (Koerner et al. 1986).

4.1.2 Mechanical Dewatering

Mechanical dewatering systems have been extensively used for conditioning municipal and industrial sludges and slurries, as well as mineral processing applications. These systems require the input of energy to squeeze, press, or draw water from the feed material. Generally, mechanical dewatering technologies can increase the solids content up to 70 percent by weight.

The performance of a mechanical dewatering system is measured by a number of parameters, including:

- Chemical conditioning dosage, measured as the mass of conditioner per mass of dry solids
- Solids capture, defined as the dry mass of dewatered solids per dry mass of solids fed into the process
- Solids content of the dewatered material

A high solids capture is desirable, because solids lost from the process (i.e., in the filtrate or centrate) represent a route for contaminant loss. Some particulate loss during mechanical dewatering is inevitable; therefore, the effluent stream will likely require further treatment.

Most mechanical dewatering processes increase the solids content of the feed material to a level comparable to that of the *in situ* sediment deposits (about 50% solids). These

dewatering processes work best with homogeneous waste streams at a constant flow rate. Because hydraulic dredging produces highly variable flow rates and solids concentrations, direct dewatering of hydraulically dredged slurries would be difficult. To accommodate this requirement, temporary storage in a tank, lagoon, or CDF is typically used to equalize flows and concentrations prior to further dewatering by one of the mechanical processes.

While a substantial amount of design and operating guidance on mechanical dewatering systems has been developed for municipal and industrial wastewater applications (EPA 1987a) and mineral processing applications (Weiss 1986), the technique has only been tested with dredged sediments on a limited scale.

- A vacuum filtration unit was tested on sediments from Toledo Harbor, Ohio (Long and Grana 1978). The solids content prior to conditioning with lime ranged from 15 to 23 percent. The post-treatment solids content was consistently above 43 percent.
- A 2.5-m belt filter press was demonstrated on sediment from the Ashtabula River in Ohio at a rate of 23 tons/hour. Solids were increased to 50 to 60 percent by weight, with solids losses of 2 to 5 percent (Rexnord, Inc. 1986).
- Bench-scale pilot study conducted by the Corps' Engineer Research and Development Center (ERDC) using sediment collected from Port Hueneme, California (Appendix A).
- Bench-scale pilot studies using material collected from Newport Bay were conducted using a 4-inch (in) hydrocyclone unit to separate sand from contaminated fine grained material (discussed later in this document and data contained in Appendix B).

4.1.3 Active Evaporating

Active evaporative technologies are different from the evaporative drying techniques used at CDFs in that artificial energy sources are used to heat the sediments, as opposed to solar radiation. Evaporation is the most expensive dewatering technology, but has been effectively used to prepare municipal sludges for incineration or for sale as fertilizer (Dick 1972). Nearly all of the water is removed, resulting in a solids content of

about 90 percent. Technologies applied to sludges that may be applicable to fine-grained sediments include:

- Flash dryers
- Rotary dryers
- Modified multiple hearth furnaces
- Heated auger dryers

The most common conventional evaporation process used for waste recycling is agitated thin-film evaporation (Averett et al. in prep.). This process is capable of handling high-solids content slurries and viscous liquids. It may also be possible to use conventional evaporation equipment commonly found in the chemical-and food-processing industries. These technologies remove water in the form of steam and may also remove volatile contaminants.

Evaporative dewatering technologies have not been demonstrated with sediments on any scale. Most of the design and operating experience and guidance on these technologies are from municipal and industrial wastewater applications (EPA 1987a).

4.2 Physical Separation Technologies

Physical separation technologies are used in sediment remedial alternatives to remove oversized material and debris in order to produce an acceptable feed material for subsequent handling and treatment. These technologies are also used to separate the sediments into two or more fractions based on physical properties or characteristics to reduce the quantity of material requiring treatment or confined disposal.

The following types of physical separation technologies may be applicable to contaminated sediments either prior to dredging or as a pre-treatment step:

- Debris removal
- Screens and classifiers
- Hydrocyclones
- Gravity separation
- Froth flotation
- Magnetic separation

Many of the physical separation technologies discussed below are mineral processing technologies, which have been widely used in the mining industry to recover valuable minerals or metals from ores. Methods such as size classification, magnetic separation, gravity separation, or froth flotation, collectively known as mineral processing, can be applied in some cases to separate contaminated sediment fractions from the bulk sediments.

4.2.1 Large Debris Removal

Because dredge sites typically contain significant quantities of large debris and oversized materials, the first step in remediation includes debris removal. Examples of debris commonly encountered during dredging include: cobbles, bricks, large rocks, tires, cables, bicycles, shopping carts, steel drums, timbers, pilings, and automobiles.

Pockets of bulk materials, such as coal or gravel, may also be encountered near docks and loading areas. The amount of debris is generally greatest in sediments along riverbanks, bridge crossings, and former industrial areas, especially where there is unrestricted public access to the waterway.

Debris can be a significant problem for a dredging operation because it can clog hydraulic cutterheads and cause bucket dredges to be raised without full closure, resulting in increased sediment resuspension. Debris can also complicate the transport of dredged sediments, possibly requiring separate handling. Large debris must be separated and removed prior to any other pretreatment or treatment process.

Debris may be separated during removal (dredging) or as part of material handling activities in between other components. For example, debris might be separated while sediments are being removed from a barge and transferred into truck trailers for transport, or while sediments are being removed from a disposal/storage area and fed into a pretreatment process. The technologies available for debris removal are relatively simple, such as a drag-line, grapple bucket, mechanical removal, and screens (discussed later).

A drag-line is a grappling hook or rake that is dragged along the river bottom with a steel cable from a boat or from a land-based winch. A grapple bucket is a specialized

crane-operated bucket, commonly used for placement of large stones, which can also be used to remove debris from a waterway.

4.2.2 Screens and Classifiers

Once the sediment has been dredged, it may still contain debris particles too large to pass through some of the separation systems (e.g., hydrocyclones). As such, an additional step is needed to screen out these materials. Grizzlies, trommels, vibrating screens, and mechanical classifiers are all widely used in mineral processing and sand/aggregate applications. Screens and classifiers may be the first units in a complex separation process or the only units in a simple process.

4.2.3 Hydrocyclones

A hydrocyclone is a high-throughput, particle-size classifier that can accurately separate sediments into coarse- and fine-grained portions. The typical hydrocyclone (Wills 1988) is a cone-shaped vessel with a cylindrical section containing a tangential feed entry port and axial overflow port on top and an open apex at the bottom (the underflow). A slurry of the particles to be separated enters at high velocity and pressure through the feed port and swirls downward toward the apex. Near the apex the flow reverses into an upward direction and leaves the hydrocyclone through the overflow. Coarse particles settle rapidly toward the walls and exit at the apex through a nozzle. Fine particles are carried with the fluid flow to the axial overflow port.

The particle size at which separation occurs is primarily determined by the diameter of the hydrocyclone. Hydrocyclones from 0.4 to 50 in (0-125 centimeters [cm]) in diameter make separations from 1 to 500 μm . The common practice is to employ several identical cyclones from a central manifold to achieve the desired capacity. Most manufacturers provide detailed manuals for selecting and sizing hydrocyclones (Arterburn 1976; Mular and Jull 1980).

The feasibility of using hydrocyclones for processing dredged material was investigated by the Corps, Buffalo District (1969) and Mallory and Nawrocki (1974). A 12-in (30-cm) hydrocyclone was tested using sediments from the Rouge River in Michigan. The physical separation was considered good, but the coarse fraction contained a large

amount of volatile solids, determined to be detritus and light organic matter (Corps, Buffalo District 1969).

Hydrocyclones were the major process unit used in a pilot-scale demonstration of particle size separation technologies conducted at Saginaw, Michigan, by the ARCS Program (Corps, Detroit District 1994) and at a similar demonstration in Toronto, Ontario (Toronto Harbour Commission 1993). At the Saginaw demonstration about 75 percent of the sediments were successfully separated into a sand fraction, reducing the concentrations of PCBs from 1.2 parts per million (ppm) in the feed material to 0.2 ppm in the sand fraction.

Recent bench scale studies conducted by the USACE suggest that sediment from the Los Angeles Region would be a suitable candidate for the use of hydrocyclones as a primary treatment technology (see Appendices B and C).

4.2.4 Gravity Separation

Gravity separators separate particles based on differences in their density. Organic contamination in sediments is often associated with solid organic material or detritus, which have much lower densities than the natural mineral particles of the sediment. Particles with high concentrations of heavy metals would be significantly more dense than the natural mineral particles. A dense media separator was used at the ARCS Program demonstration at Saginaw, Michigan (Corps, Detroit District 1994), and at the demonstration conducted in Toronto, Ontario (Toronto Harbour Commission 1993).

4.2.5 Froth Flotation

Froth flotation is used in the mining industry to process millions of tons of ore per day. Copper, iron, phosphates, coal, and potash are a few of the materials that can be economically concentrated using this process. The process is based on manipulating the surface properties of minerals with reagents so that the mineral of interest has a hydrophobic surface (i.e., lacks affinity for water) such as wax. The minerals to be rejected have, or are made to have, a hydrophilic surface (i.e., a strong affinity for water). When air bubbles are introduced, the hydrophobic minerals attach themselves to the bubbles and are carried to the surface and skimmed away.

When using flotation to remove oily contaminants from sediments, a surfactant is used in a manner that resembles a detergent. Most organic contaminants are naturally hydrophobic, and the objective in using a surfactant is to reduce the hydrophobicity of the oil phase to the point where it will be wetted by the water phase and detach itself from solid surfaces. Surfactants are able to accomplish this because such molecules have a lipophilic (fat-soluble) head, which is absorbed into the oil phase, and a hydrophilic tail, which extends into the water phase. The result of this is that the overall hydrophobicity of the oil phase is decreased. The strength of a surfactant's attachment to an oil phase is approximated by the hydrophile-lipophile balance of the surfactant. Once freed of the solid surface, an oil droplet is assisted to the surface by air bubbles and skimmed away.

4.2.6 Magnetic Separation

Magnetic separations are classified as two types depending on the intensity of the magnetic field employed (or the magnetic susceptibility of the minerals to be separated). Low-intensity separations usually employ permanent magnets, and are most often used for material coarser than about 75 μm with high magnetic susceptibility, such as iron ore. High-intensity separations that employ electromagnets are much more versatile and capable of recovering iron-stained or rusted silicate minerals from other purer, nonmagnetic phases.

Wet, high-intensity magnetic separation (WHIMS) appears to be most applicable to sediment remediation, with separations possible down to 5 μm , although at very low capacity. The WHIMS unit is essentially a large solenoid. Magnetic material is trapped on magnetized media in the chamber of the device, then flushed free in a rinse cycle when the feeding of sediment and magnetic current are stopped. Thus, the WHIMS is not technically a continuous throughput device, but operates in separate loading and rinsing cycles (Bronkala 1980). Magnetic separation was used during part of the dredging and treatment demonstration conducted with sediments from the Welland River, Ontario (Acres International Ltd. 1993).

5.0 REVIEW OF AVAILABLE TREATMENT TECHNOLOGIES

There are numerous treatment technologies for sediments contaminated with hazardous substances. Many of these technologies have been developed for treating contaminated soils at hazardous waste sites, especially those designated under the Superfund Program. This section provides an introduction to some of the better-established technologies, particularly those that have been demonstrated on contaminated sediments.

New technologies must be subjected to a lengthy process of testing and evaluation before they can be applied in a full-scale remediation project. Many innovative technologies have only been demonstrated in bench-scale (i.e., laboratory) tests, while others have undergone pilot-scale testing. In general, both bench- and pilot-scale testing of any treatment technology must be conducted prior to the application of that technology for full-scale remediation.

Sediment that is contaminated to the extent that it requires decontamination or detoxification in order to meet environmental cleanup goals may be treated by using one or more of a number of physical, chemical, or biological treatment technologies. Treatment technologies reduce contaminant concentrations, contaminant mobility, and/or toxicity of the sediments by one or more of four means:

- Destroying the contaminants or converting the contaminants to less toxic forms
- Separating or extracting the contaminants from the sediment solids
- Reducing the volume of contaminated material by separation of cleaner sediment particles from particles with greater affinity for the contaminants
- Physically and/or chemically stabilizing the contaminants in the dredged material so that the contaminants are fixed to the solids and are resistant to losses by leaching, erosion, volatilization, or other environmental pathways

Destruction technologies described in this section include thermal destruction, chemical treatment, and bioremediation; separation technologies include extraction and thermal desorption. Volume reduction using particle separation techniques discussed in previous section. Immobilization or stabilization techniques include primarily cement-based additions.

5.1 Thermal Destruction Technologies

The processes considered in this section are those that heat the sediment several hundreds or thousands of degrees above ambient temperature. These processes are generally the most effective options for destroying organic contaminants, but are also the most expensive. Included in this category are:

- Incineration
- Pyrolysis
- High-pressure oxidation
- Vitrification

Most of the thermal technologies are highly effective in destroying a wide variety of organic compounds, including PCBs, PAHs, chlorinated dioxins and furans, petroleum hydrocarbons, and pesticides. They do not destroy metals, although some technologies (e.g., vitrification) immobilize metals in a glassy matrix. Volatile metals, particularly mercury, will tend to be released into the flue gas. Additional equipment for emission control may be needed to remove these contaminants.

5.1.1 Incineration

Incineration is by far the most commonly used process for destroying organic compounds in industrial wastes. Incineration basically involves heating the sediments in the presence of oxygen to burn or oxidize organic materials, including organic compounds. A critical component of the overall treatment process is the emission control system for the gases produced by the process. Application of incineration to wet solids such as sediments is relatively uncommon; all traces of moisture must be driven off before the solids will burn. This requires the expenditure of large quantities of energy, which makes the process very expensive. Moreover, incineration tends to be a very controversial issue for communities where such facilities are to be sited because of the air emissions.

As with most processes that destroy organic compounds, incineration does not remove heavy metal contamination. Most incineration processes increase the leachability of metals through the process of oxidation (exceptions include the slagging or vitrifying technologies, which produce a nonleachable, basalt-like residue). This increased

leachability of metals would be advantageous only if the resulting ash were to be treated using a metals extraction process; otherwise, it is a distinct disadvantage. The leachability of metals is generally measured using the toxicity characteristic leaching procedure (TCLP) test. Incinerator ash that "fails" this test must be disposed of as a hazardous waste in accordance with the Resource Conservation & Recovery Act (RCRA).

5.1.2 Pyrolysis

In contrast to incineration, pyrolysis involves the heating of solids in the absence of oxygen. A pyrolysis system consists of a primary combustion chamber, a secondary combustion chamber, and pollution control devices. High temperatures, ranging from 540 to 760° C, cause large, complex molecules to decompose into simpler ones. The resulting gaseous products can then be collected (e.g., on a carbon bed) or destroyed in an afterburner at 1,200° C.

The Thermal Gas Phase Reduction Process is a specialized process in which a reducing agent (hydrogen gas) is introduced to remove chlorine atoms from PCBs or dioxins. In Hamilton, Ontario, a pilot-scale reactor was used to process PAH- and PCB-contaminated harbor sediments in July 1991. This process produced high destruction efficiencies for PAHs (99%) and PCBs (99%) in dilute sediment slurries (5-10% solids) (ELI Eco Logic International 1992). In late 1992, this technology was tested under the Superfund Innovative Technology Evaluation (SITE) Program with PCB-contaminated soil from a landfill in Bay City, Michigan (EPA 1994).

5.1.3 High-Pressure Oxidation

This category includes two related technologies: wet air oxidation and supercritical water oxidation. Both processes use the combination of high temperature and pressure to break down organic compounds. Wet air oxidation is a commercially proven technology, although its use has generally been limited to conditioning of municipal wastewater sludges. This technology can degrade hydrocarbons (including PAHs), some pesticides, phenolic compounds, cyanides, and other organic compounds (EPA 1987b). A bench-scale test using sediments from Indiana Harbor showed greater than 99 percent destruction of PAHs (EPA in prep.). However, destruction of halogenated

organic compounds (e.g., PCBs) with this process is poor. In bench-scale testing of the process conducted under the ARCS Program, using sediments from Indiana Harbor, it was found that only 35 percent of influent PCBs were destroyed (EPA in prep.). It may be possible to improve oxidation through the use of catalysts (Averett et al. in prep.).

The supercritical water oxidation process is a relatively new technology that has received limited bench- and pilot-scale testing. Available data have shown essentially complete destruction of PCBs and other stable compounds. Vendors of this process include Modar, Inc. (Natick, Massachusetts) and VerTech Treatment Systems (Air Products and Chemicals, Allentown, Pennsylvania). Modar uses high-pressure pumps and an above-ground reactor. In contrast, VerTech uses a well between 2,500 to 3,000 m deep to achieve the necessary pressures.

5.1.4 Vitrification

Vitrification is an emerging technology that uses electricity to heat and destroy organic compounds and immobilize inert contaminants. A typical unit consists of a reaction chamber divided into two sections: the upper section introduces the feed material containing gases and pyrolysis products, while the lower section contains a two-layer molten zone for the metal and siliceous components of the waste. Wastes are vitrified by passing high electrical currents through the material. Electrodes are inserted into the waste solids, and graphite is applied to the surface to enhance its electrical conductivity. A large current is applied, resulting in rapid heating of the solids and causing the siliceous components of the material to melt. The end product is a solid, glass-like material that is very resistant to leaching. Temperatures of about 1,600° C are typically achieved.

Vitrification units demonstrated in pilot- scale and full-scale tests have solidified 300,000 kg/melt. VitriFix N.A. (Alexandria, Virginia) is developing a full-scale unit for asbestos waste. Geotech Development Corp. and Penberthy Electromelt also offer vitrification systems.

In situ vitrification is a patented thermal destruction technology developed by the Battelle Memorial Institute's Pacific Northwest Laboratory. Although it was designed to

treat contaminated soils in place, it could presumably be adapted to treat dredged sediments. This technology is available commercially from Geosafe Corp., (Kirkland, Washington).

5.2 Thermal Desorption Technologies

Thermal desorption physically separates volatile and semivolatile compounds from sediments by heating the sediment to temperatures ranging from 90 to 540° C. Water, organic compounds, and some volatile metals are vaporized by the heating process and are subsequently condensed and collected as liquid, captured on activated carbon, and/or destroyed in an afterburner. An inert atmosphere is usually maintained in the heating step to minimize oxidation of organic compounds and to avoid the formation of compounds such as dioxins and furans. The temperature of the soil in the desorption unit and retention time are the primary variables affecting performance of the process. Heating may be accomplished by indirectly fired rotary kilns, heated screw conveyors, a series of externally heated distillation chambers, or fluidized beds (EPA 1991a).

5.2.1 High-Temperature Thermal Processor

The high-temperature thermal processor (Remediation Technologies, Inc. [ReTec]) uses a Holoflite™ dryer, which is a heated screw conveyor, to heat the sediment and drive off water vapors, organic compounds, and other volatile compounds. The screws for the dryer are heated by a hot molten salt that circulates through the stems and blades of the augers, as well as through the trough that houses the augers. The molten salt is a mixture of salts, primarily potassium nitrate. Maximum soil temperatures of 450° C are attainable (EPA 1992). The motion of the screws mixes the sediment to improve heat transfer and conveys the sediment through the dryer. Off-gases are controlled by cyclones, condensers, and activated carbon. This technology was evaluated in ARCS Program bench- and pilot-scale demonstrations. Removal efficiencies from 42 to 96 percent were achieved for PAHs in Buffalo River sediments (Corps, Buffalo District 1993). Greater than 89 percent of the PCBs in Ashtabula River sediments were removed by the ReTec pilot unit (Corps, Buffalo District in prep.).

5.2.2 Low-Temperature Thermal Treatment

The low-temperature thermal treatment system (Roy F. Weston, Inc. [Weston]) also uses a Holoflute™ dryer, similar to the ReTec process. However, Weston's heating fluid is a thermal oil heated by a separate, gas-fired unit. Maximum temperature for the heating fluid is a limiting factor for this process. The typical oil medium has a maximum operating temperature of 350° C, which allows soils to be heated to approximately 290° C (Parker and Sisk 1991); however, higher temperatures would likely be required to effectively remove PCBs from sediments. Vapors from the contaminated material are passed through a particulate filter, scrubbers or condensers, and carbon adsorption columns, and may require additional post-treatment. In past demonstrations, Weston has attached an afterburner to the gas stream at temperatures as high as 1,200° C to destroy the organic compounds. Removal efficiencies greater than 99 percent have been reported for volatile organic compounds; removal efficiencies of about 90 percent have been reported for PAHs (EPA 1991a). Bench-, pilot-, and full-scale units are available. The capacity of the full-scale system is 6.8 tons/hour (Parker and Sisk 1991).

5.2.3 X*TRAX System

The X*TRAX thermal desorption system (Chemical Waste Management) uses an externally fired rotary kiln to heat soil to temperatures ranging from 90 to 480° C. Water and organic compounds volatilized by the process are transported by a nitrogen carrier gas to the gas treatment system. First, a high-energy scrubber removes dust particles and 10 to 30 percent of the organic compounds. The gases are then cooled to condense most of the remaining vapors. About 90 to 95 percent of the cleaned gas is reheated and recycled to the kiln. The remaining 5 to 10 percent is passed through a particulate filter and activated carbon and is then released to the atmosphere (EPA 1992). Pretreatment requirements include screening or grinding to reduce the particle size to less than 5 cm. Post-treatment includes treatment or disposal of the condensates and spent carbon. Removal efficiencies greater than 99 percent have been demonstrated for volatile organic compounds, pesticides, and PCBs. EPA (1992) reported that mercury, one of the more volatile metals, had been reduced from a soil concentration of 5,100 ppm to 1.3 ppm using this process. The X*TRAX system is available in bench-, pilot-, and full-scale units, although this particular thermal desorption process has not been demonstrated with contaminated sediments.

5.2.4 Desorption and Vaporization Extraction System

The Desorption and Vaporization Extraction System (DAVES®) process (Recycling Sciences International, Inc.) uses a fluidized bed maintained at a temperature of about 160° C and a concurrent flow of 540 to 760° C air from a gas-fired heater. As the contaminated material is fed to the dryer, water and contaminants are removed from the solids by contact with the hot air. Gases from the dryer are treated using cyclone separators and bag houses for removal of particulates and using a venturi scrubber, counter-current washer, and carbon adsorption system for removal of water and organic compounds. Onsite treatment of liquid residues is available as a part of the process. The mobile DAVES[reg.] unit has a capacity of 10 to 66 tonnes/hour. It is applicable to most volatile and semivolatile organic compounds and PCBs (EPA 1992). The process was tested with sediments from Waukegan Harbor, Illinois, with reported reductions in PCB concentrations from 250 ppm to more than 2 ppm (EPA 1991a).

5.2.5 Low-Temperature Thermal Aeration System

The low-temperature thermal aeration system (Canonie Environmental Services Corp.) uses a direct-fired rotary dryer that can heat soil to temperatures of 430° C. The gas stream from the dryer is treated for particulate removal in cyclones and/or baghouses. Organic compounds may be destroyed in an afterburner or scrubbed and adsorbed onto activated carbon. The full-scale unit can process 11 to 15 cubic meters (m³) per hour. Effective separation of volatile organic compounds and PAHs from contaminated soils has been demonstrated (EPA 1992).

5.2.6 Anaerobic Thermal Processor Systems

The Anaerobic Thermal Processor® (ATP®) system (SoilTech ATP Systems, Inc.) also known as the AOSTRA-Taciuk process consists of four processing zones. Contaminated material is fed into a preheat zone maintained at temperatures of 200 to 340° C where steam and light organic compounds are separated from the solids. The solids then move into a 480 to 620° C retort zone, which vaporizes the heavier organic compounds and thermally cracks hydrocarbons, forming coke and low molecular weight gases. Coked solids pass to a combustion zone (650-790° C) where they are combusted. The final zone is a cooling zone for the flue gases. The organic vapors are collected for particulate

removal and for recovery or adsorption on activated carbon (EPA 1992). This system was used for the cleanup of PCB-contaminated sediments and soil from the Outboard Marine Corp. Superfund site in Waukegan Harbor, Illinois. A full-scale unit, rated at 23 tons per hour was used and produced PCB removals of 99.98 percent (Hutton and Shanks 1992). Pretreatment is necessary to reduce the feed materials to less than 5 cm in diameter.

5.3 Immobilization Technologies

Immobilization alters the physical and/or chemical characteristics of the sediment to reduce the potential for contaminants to be released from the sediment when placed in a disposal site. The principal contaminant loss pathway reduced by immobilization is contaminant leaching from the disposal site to groundwater and/or surface water; however, contaminant losses at the sediment surface may also be reduced by immobilization processes. Solidification/stabilization is a commonly used term that covers the immobilization technologies discussed in this section.

Physical stabilization processes improve the engineering properties of the sediments, such as compressive strength, bearing capacity, resistance to wear and erosion, and permeability. Alteration of the physical character of the sediments to form a solid material (e.g., a cement matrix) reduces the accessibility of the contaminants to water and entraps or microencapsulates the contaminated solids within a stable matrix. Because most of the contaminants in dredged material are tightly bound to the particulate fraction, physical stabilization is an important immobilization mechanism (Myers and Zappi 1989). Solidification processes may also reduce contaminant losses by binding the free water in dredged material (a large contributor to the initial leachate volume from dredged material in a disposal site) into a hydrated solid.

Chemical stabilization is the alteration of the chemical form of the contaminants to make them resistant to aqueous leaching. Solidification/stabilization processes are formulated to minimize the solubility of metals by controlling pH and alkalinity. Anions, which are more difficult to bind in insoluble compounds, may be immobilized by entrapment or micro-encapsulation. Chemical stabilization of organic compounds may be possible, but the mechanisms involved are not well understood (Myers and Zappi 1989).

Binders used to immobilize contaminants in sediment or soils include cements, pozzolans, and thermoplastics (Cullinane et al. 1986; Portland Cement Association 1991). In many commercially available processes, proprietary reagents are added during the basic solidification process to improve the effectiveness of the overall process or to target specific contaminants. The effectiveness of an immobilization process for a particular sediment is difficult to predict, and can only be evaluated using laboratory leaching tests.

Immobilization technologies have been evaluated for treatment of contaminated sediments from both freshwater and saltwater environments. These investigations have shown that physical stabilization of sediments is easily achieved using a variety of binders, including proprietary processes. Results of leaching tests on the solidified products have been mixed; the mobility of some contaminants has been reduced while the mobility of other contaminants has been increased (Myers and Zappi 1992). The ARCS Program evaluated solidification/stabilization of Buffalo River sediments using three generic binders: Portland cement, lime-fly ash, and kiln dust. Leaching of lead, nickel, and zinc was reduced by the cement process, but leachate concentrations of copper were significantly higher for the solidified sediments compared to leachates from the untreated sediments (Fleming et al. 1991). Immobilization of organic compounds in sediments is generally thought to be less effective than for heavy metals; however, Myers and Zappi (1989) demonstrated reductions in PCB leachability in New Bedford Harbor sediments using a solidification process. The results of these studies demonstrate the importance of laboratory evaluations of appropriate protocols for specific sediments, binders, and contaminants prior to selecting an immobilization process for remediation.

5.4 Extraction Technologies

Solvent extraction processes are used to separate contaminated sediments into three fractions: particulate solids, water, and concentrated organic compounds. Contaminants are dissolved or physically separated from the particulate solids using a solvent that is mixed thoroughly with the contaminated sediment. Most extraction processes do not destroy or detoxify contaminants, but they reduce the volume of contaminated material that must be subsequently treated or disposed. Volume reductions of 20-fold or more are possible, depending on the initial concentration of extractable contaminants in the feed material and

the efficiency of separation of the concentrated organic (oil) stream and the water evaporated by the process. Another advantage of the volume reduction is that most of the contaminants are transferred from the solid phase to a liquid phase, which is more easily managed in subsequent treatment or disposal processes. The primary application of solvent extraction is to remove organic contaminants such as PCBs, volatile organic compounds, halogenated solvents, and petroleum hydrocarbons. Extraction processes may also be used to extract metals and inorganic compounds, but these applications, which usually involve acid extraction, are potentially more costly than those used for removing organic contaminants. Solvents used for extraction processes can represent a significant cost; therefore, a key component of an extraction process is to separate the solvents from the organic compounds and reuse them in subsequent extraction steps. Usually several extraction cycles are required to reduce contaminant concentrations in the sediments to target levels.

The principal pre-treatment operation required for solvent extraction is screening or particle-size reduction to remove or reduce oversized debris (see previous section). The maximum particle size depends on the scale and configuration of the extraction process, but the recommended maximum size is 0.5 cm (EPA 1988). A wide range of solids contents are acceptable for sediment treated by extraction processes. Some processes require that the feed material be pumped, which would require that water be added to the sediment to decrease the solids content.

Extraction processes can operate in a batch mode or continuous mode. Sediments and solvents are mixed together in an extractor. Extracted organic compounds are removed from the extractor using the solvent and are transferred to a separator where the solvent and organic compounds are separated from the water and the contaminants are separated from the solvent by changes in temperature or pressure, or differences in density. Concentrated organic contaminants are usually associated with an oil phase, which is removed from the separator for post-treatment. The solvent is recycled to the extractor to remove additional contaminants. This cycle is repeated several times before the treated solids are finally removed from the extractor.

When treated solids are removed from the extractor, traces of solvent will be present. The solvents selected for these processes generally vaporize or are biodegradable. Some processes include an additional separation step designed to further remove, by distillation or other means, most of the solvent from the product solids.

A number of process options for extraction are commercially available; however, most of them are proprietary. Most of the processes discussed in this section have been used in the EPA SITE Program, and two of them have been demonstrated with contaminated sediments.

5.4.1 Basic Extractive Sludge Treatment Process

The B.E.S.T.® process (Resources Conservation Co.) uses a combination of tertiary amines, usually triethylamine (TEA), as the solvent. The first extraction is conducted at temperatures below 4° C where TEA is soluble with water and at a pH greater than 10. Hydrocarbons and water in the sediment simultaneously solubilize with the TEA, creating a homogenous mixture (EPA 1992). In the next step of the process, solids are separated from the liquid mixture by settling. The remaining solvent is removed from the solids fraction by indirect steam heating. Water is separated from the water-organic compound-TEA mixture by heating the solution to temperatures above the miscibility point (about 54° C). Organic compounds and TEA are separated by distillation, and the TEA is recycled to the extraction step. This process was demonstrated at the Grand Calumet River as a combination ARCS and SITE program demonstration in 1992 (Corps, Chicago District 1994), and bench-scale tests were performed for Buffalo River, Saginaw River, and Grand Calumet River sediments (EPA in prep).

5.4.2 CF Systems Solvent Extraction

The solvent extraction process offered by CF Systems uses compressed propane at supercritical conditions as the solvent. Sediment is screened to remove oversized material and debris and can then be pumped through the system as a slurry in a continuous mode. The solvent is mixed with the sediment under normal temperatures and high pressures. Organic compounds are extracted from the sediment and water into the solvent. The solvent-organic compound stream is removed from the extractor, and the propane is separated from the organic compounds by reducing the pressure and

allowing the propane gas to vaporize. After recompression, the gas is recycled to the extraction step. Three or more extraction stages are usually required to achieve contaminant removal efficiencies of 90 to 98 percent (EPA 1992). This process was demonstrated using contaminated sediments from the New Bedford Harbor Superfund site during a SITE Program demonstration (EPA 1990a,b).

5.4.3 Carver-Greenfield Process

The Carver-Greenfield process (Dehydro-Tech Corp.) is a physical process that can be used to separate oil-soluble organic compounds from contaminated sediments by dissolving the contaminants in a food-grade oil with a boiling point of approximately 204° C. Five to 10 kilograms (kg) of carrier oil per kilogram of solids is combined in a mixing tank where the extraction takes place. Three or more extraction stages may be necessary. From the mixing tanks, the slurry is transferred to a high-efficiency evaporator where the water is removed. The oil is separated from the dewatered solids initially by centrifugation and then by a hydroextraction process that uses hot nitrogen gas to strip the remaining oil from the solids. After separating the contaminants from the oil by distillation, the oil is recycled to the extraction step and the concentrated contaminants are further treated or disposed. Low solids content is not a problem for this process, but particle size must be reduced to less than 0.5 cm in diameter. Demonstration projects have been conducted on drilling mud wastes, a relatively fine-grain material. The requirements of this process for fine particle sizes and wet feed material favor applications to contaminated sediments.

5.4.4 Soil Washing

The term soil washing is generally used to describe extraction processes that use a water-based fluid as the solvent (EPA 1990c). Many soil washing processes rely on particle-size separation to reduce the volume of contaminated material. Other water-based techniques involve dissolving or suspending the contaminants in the water-based fluid. Because most sediment contaminants are tightly bound to particulate matter, water alone is not a suitable extraction fluid. Surfactants, acids, or chelating agents may be used with water to effect separation of some contaminants. The particle size and type of contaminant are important factors in the effectiveness of soil washing as an extraction process. Soil washing for clays and silts is only marginally applicable. The U.S. Bureau

of Mines evaluated acid extraction for heavy metals in Great Lakes sediments from three AOCs under the ARCS Program and found minor reductions in sediment metal concentrations (Allen in prep.). The use of surfactants may be successful for removing organic compounds from sandy sediments.

In the Los Angeles Region, soil washing has been proposed as an option for removing chlorides from mildly contaminated marine sediments prior to disposal in Class III upland landfills. A laboratory bench test was sponsored by the USACE in 2001 to investigate the feasibility and costs associated with soil washing using representative dredge material from the LARE. Two methods of washing were investigated: active and passive techniques, both of which proved feasible for reducing chloride leach potential in the sediments. However, while technically feasible, successful washing required very large amounts of water and throughput was quite low. Full-scale operation of the washing systems tested during the bench scale studies was predicted to cost between \$34 and \$82 per m³.

5.5 Chemical Treatment Technologies

For the purposes of this summary, the definition of chemical treatment is restricted to processes in which chemical reagents are added to a sediment matrix for the purpose of contaminant destruction. Certain immobilization, extraction, and thermal procedures also involve chemical inputs, but they are typically added to alter the phase of the contaminant, thus facilitating removal or binding the contaminant in the sediment. A clear distinction between categories cannot always be made, and some overlap may occur between this and other chapters of this document.

Chemical treatment technologies used during the removal component involve mixing chemical additives with sediments or with sediment slurry. This mixing is typically done in batch operations in some type of process vessel. Chemical treatments may destroy contaminants completely, may alter the form of the contaminants so that they are amenable to other treatments, or may be used to optimize process conditions for other treatment processes. Treated sediments may then be permanently disposed of or put to some beneficial use, depending on the nature and extent of residuals, including reagents and contaminants.

For the ARCS Program, Averett et al. (1990 and in prep.) reviewed eight general categories of chemical treatment for suitability to dredged material. Chelation, dechlorination, and oxidation of organic compounds were considered most promising. The specific processes under these three categories that have been demonstrated to be useful or that are sufficiently developed for consideration are further described in this section. Other promising, emerging technologies are also discussed.

5.5.1 Chelation Processes

Chelation is the process of stable complex formation (a chelate) between a metal cation and a ligand (chelating agent). This process could also be considered an immobilization process, and some extraction processes also use chelating agents. Binding of the metal cation in a stable complex renders it unavailable for further reaction with other reagents in chemical or biological systems. The stability of a complex generally increases as the number of bonds increases between the ligand and the metal cation (Snoeyink and Jenkins 1980). A ligand forming a single bond is known as monodentate, a ligand forming two bonds is known as bidentate, while a ligand forming more than two bonds is known as polydentate. Ethylenediaminetetraacetic acid (EDTA) is a well-known example of a polydentate ligand (Brady and Humiston 1986). PH is one of the most important parameters that affect the treatment process. Efficiency varies with the chelating agent and dosage used (Averett et al. in prep.).

The ENSOL and LANDTREAT process uses a polysilicate as an adsorptive agent (LANDTREAT) to solidify metal hydroxide silicate complexes produced by the ENSOL, which contains sodium silicate and a proprietary chelating agent. The process is carried out in an enclosed, continuous-reaction chamber (Wastewater Technology Centre 1993). The process is available at the full-scale commercial level.

5.5.2 Dechlorination Processes

Dechlorination processes remove chlorine molecules from contaminants such as PCBs, dioxins, and pentachlorophenol through the addition of a chemical reagent under alkaline conditions at increased temperatures (EPA 1990d,e). The resulting products are much less toxic than the original contaminants. Typically, chemical reagents are mixed

with the contaminated sediments and heated to temperatures of 110 to 340° C for several hours, producing the chemical reaction and releasing steam and volatile organic vapors. The vapors are removed from the processor, condensed, and further treated using activated carbon. The treated residue is rinsed to remove reactor by-products and reagent and is then dewatered prior to disposal. Adjustment of the pH of the residue may also be required. The wastewater produced may require further treatment. Processing feed streams with lower solids contents, such as sediments, require greater amounts of reagent, increase energy requirements, and produce larger volumes of wastewater for disposal, all distinct disadvantages of this process for contaminated sediments.

5.5.3 Oxidation Processes

Chemical oxidation involves the use of chemical additives to transform, degrade, or immobilize organic wastes. Oxidizing agents most commonly used (singly or in combination with UV light) are ozone, hydrogen peroxide, peroxone (combination of ozone and hydrogen peroxide), potassium permanganate, calcium nitrate, and oxygen. The use of ozone, peroxide, and peroxone has come to be known as advanced oxidation processes. Strictly defined, oxidation is the addition of oxygen to a compound (creation of carbon to oxygen bonds) or the loss of electrons from a compound (increase in the positive valence). Oxidation is used to transform or break down compounds into less toxic, mobile, or biologically available forms. Theoretically, compounds can be decomposed completely to carbon dioxide and water. Adequate process control of pH, temperature, and contact time is important to prevent the formation of hazardous intermediate compounds, such as trihalomethanes, epoxides, and nitrosamines, from incomplete oxidation.

Oxidation is commonly used to treat amines, phenols, chlorophenols, cyanides, halogenated aliphatic compounds, mercaptans, and certain pesticides in liquid waste streams (EPA 1991b). Oxidation is nonselective, and all chemically oxidizable material (including detritus and other naturally occurring organic material) will compete for the oxidizing agent. It is not applicable to highly halogenated organic compounds (Averett et al. in prep.). Certain contaminants, such as PCBs and dioxins, that will not react with ozone alone require the use of UV light with the oxidizing agent. This limits the

effectiveness of the process with slurries because the UV light cannot penetrate the mixture.

The LANDTREAT and PETROXY process uses a synthetic polysilicate (LANDTREAT) for adsorption of organic compounds to facilitate the oxidation by the PETROXY reagent, which includes a combination of hydrogen peroxide and other additives. A secondary reaction is the conversion of heavy metal cations to metal silicates on active sites of the LANDTREAT (Wastewater Technology Centre 1993).

5.6 Bioremediation Technologies

Bioremediation, sometimes called bio restoration, is a managed or spontaneous process in which microbiological processes are used to degrade or transform contaminants to less toxic or nontoxic forms, thereby remedying or eliminating environmental contamination.

Microorganisms depend on nutrients and carbon to provide the energy needed for their growth and survival. Degradation of natural substances in soils and sediments provides the necessary food for the development of microbial populations in these media.

Bioremediation technologies harness these natural processes by promoting the enzymatic production and microbial growth necessary to convert the target contaminants to nontoxic end products.

Biological treatment has been used for decades to treat domestic and industrial wastewaters, and in recent years has been demonstrated as a technology for destroying some organic compounds in soils, sediment, and sludges. Bench-scale testing of bioremediation was conducted for the ARCS Program with sediments from Great Lakes sites (Jones et al. in prep.). The chemical and physical structure of organic compounds affects the ability of microorganisms to use them as a food source. Bioremediation of organic compounds in sediment is a complex process, and its application to specific compounds is based on an understanding of the microbiology, biochemistry, genetics, metabolic processes, structure, and function of natural microbial communities. Microbiology must be combined with engineering to develop effective bioremediation processes. The ARCS Program conducted a workshop on bioremediation of contaminated sediments to document laboratory research and field applications of this technology. The proceedings of this workshop (Jafvert and

Rogers 1991) provide an excellent discussion of the state of the art with an emphasis on the microbial and chemical processes involved.

Many of the more persistent contaminants in the environment, such as PCBs and PAHs, are resistant to microbial degradation because of (1) the compound's toxicity to the organisms; (2) preferential feeding of microorganisms on other substrates; (3) the microorganism's lack of genetic capability to use the compound as a source of carbon and energy; or (4) unfavorable environmental conditions in the sediment for propagating the appropriate strain of microorganisms. Alteration of the environmental conditions can often stimulate development of appropriate microbial populations that can degrade the organic compounds. Such changes may include adjusting the concentration of the compound, pH, oxygen concentration, or temperature, or adding nutrients or microbes that have been acclimated to the compound.

Biodegradation of refractory organic compounds is not uncommon in nature, but can take many years. The key to improving the usefulness of bioremediation for cleaning up contaminated sediment sites is to determine how to accelerate the rate of biodegradation to detoxify the target compounds in a finite time period (i.e., weeks or months rather than years).

Ideally, biodegradation of organic compounds in sediments would be accelerated *in situ*. However, because of the complexity of the sediment-water ecosystem; the difficulties in controlling physical and chemical, as well as biological, processes in the sediment, and the need to adjust environmental conditions for various stages of the biodegradation process; limited effectiveness has been demonstrated for *in situ* bioremediation. Much research is underway in the area of *in situ* treatment, and future efforts will likely overcome some of these difficulties for certain sites and specific contaminants. However, the best current prospects for successful bioremediation of xenobiotic compounds are engineered treatment systems in which environmental conditions can be carefully controlled and adjusted as the biotransformation processes progress with time.

Biodegradation is accomplished either aerobically or anaerobically. Aerobic respiration is energy-yielding microbial metabolism in which the terminal electron acceptor for substrate

oxidation is molecular oxygen, and carbon dioxide and water are the end products. Free oxygen must be present for aerobic reactions to occur. Anaerobic respiration is energy-yielding metabolism in which the terminal electron acceptor is a compound other than molecular oxygen, such as sulfate, nitrate, or carbon dioxide, and methane, sulfides, and organic acids are the typical end products. Aerobic processes generally proceed more quickly and provide a more complete degradation of the organic compounds than anaerobic processes. However, some compounds can only be changed by anaerobic organisms. For example, dechlorination of the more highly chlorinated PCBs by anaerobic processes has been demonstrated in laboratory and field studies. On the other hand, the less chlorinated PCBs are susceptible to degradation by aerobic organisms. Sequential anaerobic treatment followed by aerobic processes appears to offer an effective destruction technology for PCBs (Quensen et al. 1991).

This section addresses surface bioremediation techniques in which sediments are removed from the waterway and treated in bioslurry reactors, contained land treatment systems, compost piles, or contained treatment facilities (CTFs). Pretreatment requirements for these processes include removal of oversized particles for bioslurry reactors and possible adjustment of solids content for all of the processes. One of the advantages of bioremediation technologies is that the physical and basic chemical characteristics of the treated sediments are very similar to the feed material, allowing a wide range of choices for beneficial use of the treated sediment.

5.6.1 Bioslurry Processes

Bioslurry reactors are a relatively new technology that has been applied to contaminated solids mostly in the last 5 to 10 years. There have been a number of pilot-scale applications, but few full-scale installations. Bioslurry reactors are best suited to treating fine-grained materials that are easily maintained in suspension. In a bioslurry system, a sediment-water slurry is continuously mixed with appropriate nutrients under controlled conditions in an open or closed impoundment or tank. Aerobic treatment, which involves adding air or another oxygen source, is the most common mode of operation. However, conditions suitable for anaerobic microorganisms can also be maintained in the reactor where this oxic state is an essential step in the biodegradation process. Sequential anaerobic/aerobic treatments are also possible in these systems.

Contaminants with potential for volatilization during the mixing and/or aeration process can be controlled using emission control equipment.

Systems for treating soils or sediments are often operated in batch mode, because typical retention times are on the order of 2 to 12 weeks. Once the treatment period is completed, the solids may be separated from the water and disposed of separately. The slurry solids concentrations range from 15 to 40 percent; therefore, adjustments in solids contents for slurry treatment of sediments may be minor.

The degradation of PCBs using the bioslurry reactor technology was investigated by General Electric Co. (Abramowicz et al. 1992). Researchers concluded that between 35 and 55 percent of the initial PCBs were degraded over a 10-week test period in reactors amended with biphenyl. Remediation of contaminated sediments from Toronto Harbor, Ontario, was tested in pilot-scale reactors in 1992 (Toronto Harbour Commission 1993). Although complicated by analytical interferences, the results showed that oil and grease were completely degraded in several weeks' time, with a partial degradation of PAHs.

5.6.2 Contained Land Treatment Systems

Contained land treatment systems, which have been demonstrated in Europe, require mixing of appropriate amendments with the sediments, followed by placement of the material in an enclosure such as a building or tank and on a pad or prepared surface (EPA 1991c). The enclosure protects the material from precipitation, moderates temperature changes, allows moisture control, and provides the capability to control volatile organic compound emissions.

Leachate from the sediment is collected by underdrains for further treatment as necessary. The layer of sediment treated for each lift is generally no deeper than 6 to 8 in (15-20 cm). Regular cultivation of the sediments and the addition of nutrients, and in some cases bacterial inocula, are typically required to optimize environmental conditions for rapid bioremediation. The excess water associated with the sediment as it is placed in the treatment bed may create operational problems for startup and will likely require that the system be designed for lateral confinement of the material.

5.6.3 Composting

Composting is a biological treatment process used primarily for contaminated solid materials. Bulking agents (e.g., wood chips, bark, sawdust, straw) are added to the solid material to absorb moisture, increase porosity, and provide a source of degradable carbon. Water, oxygen, and nutrients are needed to facilitate bacterial growth.

Sediment solids contents will likely be sufficient for composting operations, and in some cases dewatering of the sediment may be necessary as a pretreatment step. Available composting techniques include aerated static pile, windrowing, and closed reactor designs (EPA 1991c).

Volatilization of contaminants may be a concern during composting and may require controls such as enclosures or pulling air through the compost pile rather than pushing air into and out of the pile. Use of composting to treat sediments should increase permeability of the sediment, allowing for more effective transfer of oxygen or nutrients to the microorganisms. A pilot-scale demonstration of composting is being conducted for Environment Canada's Cleanup Fund at a site in Burlington, Ontario.

Approximately 150 tonnes of PAH-contaminated sediments from Hamilton Harbor were placed in a temporary shelter and tilled periodically with additions of a proprietary organic amendment (Seech et al. 1993). The treatment was executed over an 11-month period. Sediments that were tilled with the amendment showed reductions of PAHs of over 90 percent, while controls with tillage and no amendment showed reductions of 51 percent. Controls with no tillage or amendment showed reductions of 73 percent (Grace Dearborn Inc. in prep.).

5.6.4 Contained Treatment Facility

CDFs routinely used for dredged material may be used as CTFs for bioremediation of sediments. These facilities often provide long-term to permanent storage. The size of the CDF and the depth (1.5-5 m) of sediments may limit the capability to control conditions compared to other bioremediation systems. These limitations are similar to those for *in situ* bioremediation processes for contaminated soil sites, except that engineering the biotreatment system for upland CDFs is not as difficult compared to *in situ* systems.

A pilot evaluation of a contained treatment facility for PCB-contaminated sediments is underway at the Sheboygan River AOC. Rather than a diked disposal facility, the contained treatment facility is constructed with sheet pile walls and includes an underdrain system that could be used for leachate control and to add nutrients, oxygen, and other additives. The ARCS Program has contributed to the scientific assessment of the operation; a report documenting these investigations will be published at a later date; however, these experiments were inconclusive as of early 1994. Bioremediation in a CDF would offer an economical process for reducing sediment organic contamination, but more research is needed to develop techniques for implementation.

6.0 EVALUATION OF TREATMENT ALTERNATIVES

Section 3 provides a review of dredge material characteristics for the contaminant-prone areas that the USACE is responsible for maintaining. Typical USACE dredge material from these areas is comprised mostly of sand, has high trash/debris content, and usually has less than 20 percent fine-grained silts and clays. Most of the areas are depositional and located at the base of rivers or flood control channels. Contaminants of concern typically include metals, PAHs, pesticides, and PCBs with concentrations that would be considered mildly impacted. Bulk sediment concentrations generally exceed lower range threshold screening values (e.g., ER-Ls), but are typically below higher threshold screening values (e.g., ER-Ms). More importantly, portions or all of the material from these locations frequently exhibit bulk sediment toxicity making them unsuitable for unconfined open ocean disposal.

One of the goals for a regional treatment facility is to produce a reusable by-product to help offset treatment costs, reduce the amount of material for upland or contained disposal (e.g., CAD or CDF), and support the CSTF's goal for promoting beneficial reuse in the region. Sediments typically dredged by the USACE contain 80 percent or more sand content. Since regional beach nourishment projects are in high demand, it seems practicable to design a facility to recover clean course sands that can be used for beach nourishment. Doing so would leave a concentrated, fine-grained sediment slurry to manage or for further treatment to produce a secondary beneficial by-product.

With these goals in mind, Sections 4 and 5 reviewed available pre-treatment and treatment technologies for potential use within an upland regional sediment treatment facility for Southern California contaminated sediments. The remainder of this section evaluates each of these options for further consideration. Treatment technologies that have the potential for use as economically viable and environmentally protective alternatives are then carried forward into Section 7, where treatment facility design criteria are discussed.

6.1 Pre-Treatment Technologies

The following pre-treatment technologies were identified and discussed in Section 4:

- Dewatering
 - Passive
 - Mechanical

- Active evaporating
- Physical Separation
 - Debris removal
 - Screens and classifiers
 - Hydrocyclones
 - Gravity separation
 - Froth floatation
 - Magnetic separation

Recent studies conducted by the USACE (see Appendix B and C) suggest the use of one or more modified pre-treatment technologies may actually be sufficient for primary treatment of regional contaminated sediments. The use of hydrocyclones combined with mild washing has been shown to effectively isolate courser sand particles and reduce contaminant concentrations to produce a material likely suitable for nearshore placement or beach nourishment. As such, one or more pre-treatment technologies would be beneficial for use in designing a regional treatment facility.

Depending on the treatment technique selected, de-watering may or may not be needed. However, given the high trash/debris content at the two primary USACE contaminated sediment dredge sites (LARE and Marina del Rey), an initial debris removal step would be beneficial prior to processing. This could be accomplished using large mesh screens or a macerator to shred the material for removal using a scalper or small mesh (2000 μ) shaker screen.

Physical separation using one or more of the technologies mentioned above would likely be the next step in the treatment process. The laboratory and field pilot studies conducted by the USACE employed the use of screens and hydrocyclones to accomplish this task, although other technologies may be just as effective. Recent work completed for the Fox River (Shaw Environmental 2005) used a flotation process to separate sand from the finer grained components, however, tests to confirm potential reductions in chemical concentrations have not yet been conducted locally to verify if this process would be suitable for the proposed application.

6.2 Treatment Technologies

The following treatment technologies were identified and discussed in Section 5 as potential options for a regional contaminated sediment treatment facility:

- Thermal Destruction
 - Incineration
 - Pyrolysis
 - High-pressure oxidation
 - Vitrification

- Thermal Desorption
 - High-temperature thermal processor
 - Low-temperature thermal processor
 - X-TRAX system
 - Desorption and vaporization extraction system
 - Aerobic thermal processor systems

- Immobilization
 - Cement-based additions

- Extraction Technologies
 - Basic Extractive Sludge Treatment (BEST) process
 - CF Systems solvent extraction
 - Carver–Greenfield process
 - Soil washing

- Chemical Treatment
 - Chelation processes
 - Dechlorination
 - Oxidation

- Bioremediation
 - Bioslurry
 - Contained Land Treatment Systems

- Composting
- Contained treatment facility

The use of thermal destruction and desorption technologies for treating contaminated sediments in Southern California does not appear to be warranted considering that they were developed primarily for sediments with much higher contaminant concentrations, require infrastructure that is very costly to construct and operate, and produce a glass like by-product that is not readily marketable in the region (GeoSyntec Consultants). As such, these technologies were not carried forward for further consideration in designing a regional treatment facility.

The use of cement-based additions to immobilize contaminants and produce a high quality fill material from impacted dredge materials has been evaluated by many researchers, including studies conducted for the USACE using sediments collected within the study area (USACE 2002), and found to be very effective. The cost to implement this technology is approximately \$45/m and recipients for the treated material are available within close proximity of the dredge locations (i.e., ports and landfills). This technology is, therefore, carried forward as a viable alternative for use in a regional treatment facility.

Most extraction technologies rely on the use of solvents to strip the contaminants from the sediment particles, producing a “washed” sediment fraction and a contaminated solvent waste stream in the process. A recent field pilot study conducted by the USACE (Appendix C) revealed that a simple seawater rinse, used in conjunction with a hydrocyclone particle sorting process, was sufficient to significantly reduce contaminants and did not produce solvent wastes requiring further management. Because sediment contaminant concentrations for the USACE dredge areas are typically low, sediment washing/extraction technologies using anything more aggressive than water or mild detergents is not expected to be necessary. As such, most of the proprietary processes described in Section 5 are not warranted for use in this region for typical USACE dredge material.

The chemical treatment technologies discussed in Section 5 and mentioned above were developed for use with one or more specific classes of compounds. Typical contaminated dredge material from within the USACE study area reflect the results of urban runoff and frequently contain mixtures of contaminants such as metals, PAHs, pesticides, and PCBs. The use of one or more of these technologies to treat the dredge materials may be suitable for reducing contaminant levels, but would not remove trash and organic debris or make it more suitable for beneficial reuse. As such, the material would still need to be disposed of at an upland landfill since ocean disposal is only considered appropriate for un-altered dredge materials.

Bioremediation technologies have been successfully used for treating many organic contaminants, but are not as effective for use with inorganics (i.e., metals). Typical USACE contaminated dredge material contains elevated concentrations of both organic and inorganic contaminants; therefore, bioremediation approaches may not be sufficient for use singly. Further, these technologies typically require large stock pile areas for treatment, which is a limiting factor for all of Southern California. Space is a premium throughout the study area and treatment technologies that require large work areas for processing and storage will not be given a high priority for implementation.

6.3 Evaluation Summary

Table 6-1 summarizes the evaluation of pre-treatment and treatment technologies discussed in Sections 6.1 and 6.2, adding information related to potential treatment costs and overall impacts. In consideration of the physical characteristics of typical dredge material for which the USACE is responsible within the Los Angeles Region (Section 3), and the review of available treatment technologies presented in Sections 4 and 5 (summarized in Section 6.2) the following approach is recommended for use to implement a regional sediment treatment facility:

- Step 1 – Screens to remove large trash and debris
- Step 2 – Physical particle separator to remove the coarse sands
- Step 3 – Cement-based binders to fix or stabilize fine-grained materials
- Step 5 – Process water treatment or reuse

Table 6-1
Evaluation Summary of Pre-Treatment and Treatment Technologies

(Pre)Treatment Technology	Effectiveness		Technical Difficulty	Land Requirements	Potential Impacts	Relative Cost ³
	Organics	Inorganics				
Active/Passive Dewatering	NA ²	NA ²	Min	Min to Very Large	Water	Low
Physical Separation	Good ¹	Good ¹	Min	Min to Medium	Water	Low
Thermal Destruction	Good	Marginal	Medium	Medium	Air	High
Thermal Desorption	Good	Marginal	Medium	Medium	Air	High
Immobilization	Good	Good	High	Medium to Large	Air	Medium
Extraction Technologies	Good	Good	High	Medium to Large	Water	High
Chemical Treatment	Good	Good	High	Medium to Large	Water, Air	High
Bioremediation	Good	NA ²	Medium	Large	Water, Air	Low

¹ Technology removes contaminants from sand fraction only, fines remain contaminated.

² NA = Not applicable or effective treatment approach.

³ Costs presented within relative ranges where Low = <\$25/yard; Medium = \$25-\$50/yard; High = >\$50/yard.

Most of dredge areas within the USACE's purview can be classified as having a high trash and debris load that must be removed prior to processing. As such, some form of mechanical screening will be needed. USACE dredge material also typically contains a high sand content which can provide both a beneficially reusable source material as well as a way to reduce the volume of material for disposal or some other means of treatment. To accomplish this, some form of physical separation process will be required to separate the cleaner sand fraction from the contaminated finer-grainer material. Lastly, the remaining material will need to be either treated to remove contaminants or dewatered for upland disposal.

None of the specific treatment techniques discussed in Section 5 are particularly well-suited for this material due to their high operating costs and inability to treat both inorganic and organic based contaminants. USACE dredge material is considered mildly contaminated (Section 3) with chemical concentrations significantly below RCRA hazardous waste thresholds. Therefore, once dewatered, this material is usually suitable for disposal at a Class III landfill, without any additional form of treatment. This basic approach is further elaborated in the following section and specific design and siting considerations are discussed.

7.0 DEVELOPMENT OF A REGIONAL TREATMENT FACILITY

Recent activities of the Los Angeles CSTF include developing a long-term contaminated sediment management strategy (CSTF 2005) which relies heavily on the notion of balancing beneficial reuse options against aquatic disposal options for contaminated materials. It is anticipated that a similar approach will be included in the Los Angeles Regional DMMP which is in preparation by the USACE. Previous activities of the CSTF and USACE related to this topic have been limited to researching potential markets for treated contaminated sediments in the Los Angeles Region. To date, no studies have been conducted specifically to evaluate feasibility and costs associated with developing a regional facility dedicated to storing and/or treating dredge materials for beneficial reuse within the region.

Evaluated individually, contaminated sediment treatment alternatives almost always cost more than aquatic disposal or nearshore fill options. In an effort to identify ways to promote treatment and beneficial reuse in the County, the CSTF members developed a concept for a regional processing facility where sediments could be stored, treated and then reused, on an as needed basis, in various upland applications such as fill material, cement products, landfill daily cover, roadway base material, etc. This concept offers the following advantages:

- Capital development costs can be amortized for the facility over multiple projects/years vs. each project;
- Provides ability to develop larger processing facility which will lower per unit treatment costs;
- Provides opportunity to combine disposal permitting efforts by maintaining a single user permit for operating the facility;
- Allows for temporary storage of dredge material so that treatment can occur independent of dredging;
- By storing and treating the material over longer timeframes it will provide for a more constant supply of end use products for export;
- Locating the facility near regional distribution points (e.g., rail lines or waterways) will provide for greater opportunities to locate end users; and
- Provides a long-term and environmentally protective solution to the regional problem of contaminated sediment disposal.

7.1 Site Requirements

Based on an initial evaluation of project opportunities and constraints, the following list of processing site location qualities has been developed:

- Processing site must be in close relative proximity to the majority of the target dredge areas to minimize transport or pumping costs
- Processing site must allow for quick and easy transport of dredge materials to the facility, without impacting local infrastructure (roads) and air quality
- Processing site must allow for wastewater elimination during dewatering step
- Processing site must be located in area that provides for easy transport of treated material to target markets (e.g., roadway developed for haul truck passage, railroad lines, waterfront access)
- Processing site must not be located in area where high noise levels or potential offending odors resulting from organic-rich sediment will cause adverse impacts to nearby residences
- Processing site must be located in area not containing sensitive habitat or groundwater resources
- Processing site lease/purchase rates must be competitive to allow for cost-effectiveness
- Processing site must contain sufficient space for storage of bulk sediment, treatment equipment, and final product storage

7.2 Location

Taking into consideration the target site qualities discussed in Section 7.1, potential processing site options were researched and two categories were identified for the Los Angeles Region: (1) mobile barge mounted systems that could be transported to the dredge site (e.g., as was used for the study presented in Appendix C); and (2) one or more upland locations which provide either direct or adjacent waterfront access. Based on the criteria presented above, potential upland regional locations include:

- Upland property located along the non-residential, lower portion of the Los Angeles River where a pipeline could be used to transport the dredge materials further inland;
- Any one of the THUMBS energy islands located in Long Beach;
- Upland property located at the Seal Beach Naval Weapons Facility;

- Upland property located within the ports of Los Angeles or Long Beach;
- New land created by the City of Long Beach adjacent to the City's harbor marina; or
- New land created by the County on or near the break water jetty at Marina del Rey.

7.3 Treatment Approach & Facility Design

Under either upland or barge mounted scenarios, sediment processing at a regional facility would likely consist of a series of mechanical and/or chemical systems to first extract potentially reusable material (e.g., sand) and then to treat the remaining material to render it inert for disposal or upland reuse applications. The specific design of the treatment system may vary depending on the physical characteristics of the material (i.e., sand content, presence of debris) and method for delivery to the site (i.e., hydraulically pumped vs. mechanical clamshell). Regardless of the specific equipment, the treatment process will likely include some common design elements. Figures 7-1 and 7-2 provide example scenarios for sediment processing considering hydraulic and mechanical dredging sources.

Both approaches include a mechanism for creating a sediment slurry of approximately 10 to 15 percent solids and then passing the material through screens and a macerator to remove large debris and grind up the smaller debris items. This material is then removed using a scalper so that the feedstock to the hydrocyclones is free of trash and debris. Next, a series of hydrocyclones can be used to separate the clean sand from the finer-grained, and more contaminated particles. The washed sand can then be exported as clean fill material or for beach nourishment. If needed, the residual slurry can be reused for suspending additional sediments, creating a closed treatment system or discharged to a settling tank to separate the fine grained particles from the overlying water.

Slurry water treatment will likely require a multi-step process that begins with gravity settling. This process may be aided by the addition of flocculants to the water to speed up the process. Once settling has occurred, the overlying water may or may not be suitable "as is" for discharge. If the water is determined not to be suitable, additional treatment steps may be needed such as media filters, carbon or resin beds, or the addition of chemicals to bind up and settle any remaining contaminants (e.g., EDTA for metals).

Figure 7-1
Sediment Treatment and Reuse Site Treatment Design Option #1 (Hydraulic Dredging)

Figure 7-2
Sediment Treatment and Reuse Site Treatment Design Option #2 (Mechanical Dredging)

The fine-grained, contaminated, sludge remaining in the settling tanks would then be removed and dewatered for disposal. Active dewatering can be accomplished physically by using belt presses or centrifuges, or chemically using cement-based binders. Passive dewatering can be accomplished by simply allowing the material to air dry. Two advantages of using cement-based binders to dewater the sludge is that they will (1) bind up most of the contaminants in the process and allow the material to be disposed of more easily, and (2) the treated material will exhibit much greater geotechnical strength which could allow the material to be used as sub-base fill material.

Using these conceptual treatment designs, example facility layouts are presented for three potential facility locations: City of Long Beach upland facility, City of Long Beach shoreline facility and Marina del Rey breakwater facility; each presented in Figures 7-3 through 7-5.

7.4 Construction and Permitting

Because the USACE (federal government) is not responsible for dredge material treatment and/or disposal, treatment facility construction would need to be designed and funded by one or more of the local dredging sponsors (e.g., City of Long Beach, the County, POLA, POLB, etc.). Facility development would require the same local, state, and federal permits as any other capital development project. If the selected treatment design includes provisions for ongoing process water discharge, a National Pollutant Discharge Elimination System (NPDES) discharge permit will likely be required by the California State Water Quality Control Board.

7.5 Models for Long-Term Management & Operation

The development and use of regional sediment treatment facilities is rare in the United States so finding a suitable model to base the current proposal on is difficult. Currently, the Los Angeles CSTF members, including the USACE have considered the following potential multi-use disposal scenarios for the region.

- CDF
- Confined Aquatic Disposal (CAD)
- Shallow Water Habitat Creation
- Upland Re-Handling/Processing Facility
- Upland Gravel Pit Disposal

Figure 7-3
Anaheim Street Site

Figure 7-4
Long Beach Marina Site

Figure 7-5
Marina del Rey Site

While all five of these options have the potential to support disposal or processing by multiple parties, they can actually be separated into two categories, each with very different characteristics and ownership/management issues. A CDF or shallow water habitat is not really a multi-user facility, but rather an individually permitted project that occasionally allows disposal by multiple parties on an opportunistic basis. On the other hand, a CAD, upland re-handling facility, or upland gravel pit could easily be operated as multi-user disposal or processing facilities. Consider the following comparisons and contrasts:

Project Specific/Single User Site for Disposal or Beneficial Reuse (CDF, shallow water habitat)	Long-Term/Multi-User Site for Disposal or Beneficial Reuse (CAD, upland re-handling facility, upland gravel pit disposal)
Individual project permitted based on specified fill material.	Open-ended permit with range of material types authorized for disposal.
- Schedule driven by development plans and contract duration (typically, speed is of the essence to reduce costs). - Very narrow window of opportunity for disposal by other parties.	- Schedule driven by capacity. - No disposal or processing windows. - Typically permitted for disposal or processing for many years or decades.
Monitored during construction and possibly upon completion.	Monitored routinely during operation (i.e., commercial landfill) for regulatory compliance.
- No tipping fees typically collected. - Project cost is fixed and use of other fill material may offset import fill costs.	Tipping fees common to offset capital and management costs or facility operated for profit.
Contractor carries insurance bonds during construction to manage liability.	Owner/operator maintains long-term liability insurance similar to landfill.

Both CDFs and shallow water habitat areas have been designed and constructed within the region so management strategies already exist for those scenarios. Many of the capital improvement projects (i.e., terminal development) within the POLA and POLB include the use of CDFs, and at least two examples exist for the development and creation of shallow water habitat areas (Cabrillo and Pier 400). For both options, there are no outstanding ownership or management issues to resolve. Land is either privately owned or leased from the State of California and environmental impact assessments are conducted prior to construction and certified by the project proponent or CCC. Permit applications are reviewed and approved by the California State Water Quality Control Board, EPA, and the Corps and disposal occurs as a single action. Long-term management is typically not required to monitor for contaminant release, but is frequently conducted to evaluate biological re-colonization.

True multi-user disposal/treatment sites (i.e., CAD, upland re-use facility, and upland gravel pit disposal) have not been developed with the region and there are no examples for suitable management and operation. Some of the unresolved issues associated with these sites include the following:

- No local sponsor(s) have been identified to fund or develop the site
- A suitable site has not yet been identified
- Questionable market locally (per GeoSyntec Report for CSTF)
- Suitable processing technology not yet confirmed
- Operational and long-term liability
- Groundwater protection
- Host jurisdictions
- Environmental monitoring not defined
- Corrective action triggers and actions
- Administrative costs

7.6 Action Plan for Implementation

While some advances have been made with regard to the development of treatment technologies (see Appendices B and C), many unresolved tasks remain prior implementing a regional contaminated sediment treatment facility. Although not inclusive, the following action items have been identified:

- Identify a local sponsor and/or developer;
- Identify a suitable location for the facility;
- Finalize the design for treatment technologies to be included at the facility;
- Identify and secure applicable environmental permits, development permits, etc.;
- Develop an operations and management plan for the facility;
- Develop and materials management and disposal plan for the facility;
- Identify insurance and liability requirements and draft legal agreements for material transfer; and
- Assuming that the primary byproduct from the facility will be clean sand, coordinate site development with regional beach renourishment representatives (e.g., USACE, City of Long Beach, Los Angeles County Beaches and Harbors, SANDAG) to identify and rank beach disposal needs and volumes.

8.0 CONCLUSIONS AND RECOMMENDATIONS

Based on the review of available treatment technologies presented in Section 7, and the results of the pilot treatment studies presented in Appendices A through C, one or more sediment pre-treatment technologies should be sufficient for use as a regional treatment approach for contaminated marine sediments within the Los Angeles Region. The use of shaker screens and hydrocyclones to separate and recover clean, coarse sands from contaminated dredge material has been proven to be highly effective at producing a reusable sand product for beneficial reuse, while at the same time reducing the volume and weight of contaminated sediment requiring disposal.

These results further suggest that, with minor refinements, this process can provide an economical approach for sediment treatment at one or more regional processing facilities such as that described in Section 7. Preliminary cost estimates suggest a range of between \$10 to \$20/yard to operate a hydrocyclone sand separation facility capable of processing 2,000 yards/day of contaminated material, not including disposal fees for the dewatered, fine-grained contaminated fraction. Recommendations for moving forward include the following administrative and technical action items:

Administrative Action Items

- Identify a local sponsor and/or developer;
- Identify a suitable location for the facility;
- Identify and secure applicable environmental permits, development permits, etc.;
- Develop an operations and management plan for the facility;
- Develop and materials management and disposal plan for the facility;
- Identify insurance and liability requirements and draft legal agreements for material transfer; and
- Assuming that the primary byproduct from the facility will be clean sand, coordinate site development with regional beach renourishment representatives (e.g., USACE, City of Long Beach, Los Angeles County Beaches and Harbors, SANDAG) to identify and rank beach disposal needs and volumes.

Technical Action Items:

- Finalize the design for hydrocyclone/washing treatment technologies to be included at the facility;
- Develop disposal and/or reuse options for the dewatered sludge material;
- Develop a wastewater treatment system to allow for direct discharge of treatment water; and
- Conduct additional full-scale pilot studies at upland locations to refine bulk sediment handling and slurry tank practices.

APPENDIX A
WET SIEVING SAND SEPARATION LABORATORY PILOT STUDY

Sand Separation in Estuarine Sediments and Mechanical Dewatering for Management of Fine Residuals - Bench Scale Feasibility Testing

¹TRUDY OLIN-ESTES, P.E.[†], SUSAN BAILEY^{††}, RICHARD SHAFER, P.E.^ψ, JIM FIELDS[¶], STEVE CAPELLINO^{¶¶}

ABSTRACT Recovery of sand for beneficial use, with mechanical dewatering of fine residuals, is one dredged material management alternative under consideration by the United States Army Corps of Engineers (USACE) Los Angeles District. Bench scale testing was conducted to model hydrocyclone separation and plate and frame dewatering. Coarse and fine fractions were separated by wet sieving. Contaminant analysis revealed little variation between fractions in concentration of PCBs, pesticides, oil and grease and TOC, although the concentration of silver in the fines cake was approximately nine times higher than in the sand. Flocculants were tested on the fine slurry to assess the improvement in drainability of the sediment. Dewatering testing was conducted using a bench top recessed chamber press. Differences in cycle time, cake properties, and filtrate quality were assessed for selected filter fabrics, slurry concentrations and flocculent dosages. Gravity drainage was improved with the addition of flocculent, but dewatering cycle times and cake quality were comparable for all combinations tested. Higher suspended solids were observed in the pressate of unflocculated sediment, but decreased markedly once a cake was formed. Lengthy cycle times, while not directly scalable, indicate large press capacity would be required in order to couple the dewatering circuit with a typical dredging operation.

INTRODUCTION

The Los Angeles District of the Corps of Engineers is actively engaged in evaluation of innovative treatment and management alternatives for dredged material. Navigation dredging is scheduled for FY2005 in Marina del Rey and Port Hueneme. A sizeable portion of the sediments there are predominantly sandy in composition, with some contaminated fines. The District is interested in evaluating the feasibility of recovering the sand using hydrocyclones, and investigating treatment and dewatering alternatives for the residual fine materials. Approximately 40% of the total dredging scheduled for FY05 is projected to be suitable for treatment (about 15-25K m³).

A bench scale laboratory study was conducted using a blended composite of materials from both sites. The principal objective of the study was to simulate a treatment train for separation of sand and dewatering of the fines. Studies were structured to provide information regarding contaminant distribution in the sediments, dewaterability of the material, conditioning requirements, filtrate quality, and weight and volume of process streams.

Methods and Materials. Sediments were obtained from Port Hueneme (PtH) and Marina del Rey (MdR) and transported in food grade plastic containers or HDPE buckets packed in ice. Samples were logged in, temperature was checked, and they were placed in a cooler at 4° C. All of the Port Hueneme sediment (~49 L or 13 gal) was combined with the Marina del Rey sediment (~34 L or 9 gal) to produce a homogeneous sediment of sufficient volume for the planned testing, with a measurable PCBs concentration. Mixing was done using a Hobart industrial mixer with stainless steel bowl. Samples of homogenized sediment were taken for analysis as specified in Table A-1. A small pore water sample was obtained for salinity testing by allowing the sediment to consolidate in the cooler for a period of time following homogenization. Samples of the bulk sediment obtained for geotechnical testing were packaged separately and taken for immediate analysis. Samples obtained for chemical analysis were stored at 4° C without preservatives prior to analysis. With the exception of the initial screening analysis to determine sediment suitability for testing, all samples were stored and submitted to the laboratory for analysis as a single batch in order to minimize variability in the results due to differences in sample preparation, calibration, and instrumentation.

Table A-1
Schedule of Chemical and Physical Analysis

Sample	Replicates	Analyses	Method
Bulk sediment	2	PCB aroclors and Total PCBs	SW-846 8082
	2	Organochlorine Pesticides	SW-846 8081
	2	Organophosphorus Pesticides	SW-846 8141
	2	Oil and Grease	EPA 418.1
	2	TOC	SW-846 9060
	2	Silver (Ag)	SW846 6010B/6020
	2	Soot	Gustafsson et al 1997
	1	Wet bulk density	Gravimetric ¹
	1	Grain Size (Sieve and Hydrometer)	ASTM D422
	1	Specific Gravity (Sp. Gr.)	MD0302
	1	Fraction Organic	ASTM D2974
	3	Water Content	ASTM 2216
	3	Particle size analysis	Coulter Counter
Pore water	1	Salinity	YSI Incorporated Salinity Meter Model 30/10 FT

1 Wet bulk density as determined gravimetrically was checked against bulk density calculated using theoretical pore volume, solids volume relationships. The methods are further described in the text.

Fractionation. Homogenized sediment was separated by wet sieving. Small samples were sieved on 4.75 mm, 500 μ m, 250 μ m and 75 μ m sieves for visual identification of organic and carbon phases. Larger samples were sieved on 4.75 mm and 75 μ m (200-mesh) sieves to produce material for flocculent and dewatering testing. These sieve sizes correspond to the boundaries of sand as determined by the Unified Soil Classification System (USCS). Salinity of tap water used for wet sieving was adjusted with Instant Ocean® to the approximate salinity of site water (34 ppt), so that contaminant solubilization would be representative of that expected in the field. Material >4.75 mm was designated as oversize and discarded.

Duplicate samples of the sand fraction (material retained on the 200-mesh sieve) were obtained and stored at 4° C prior to analysis. Slurry passing the 200-mesh sieve was retained for flocculent and dewatering testing. Samples of the fine fraction were later taken from the dewatered cake for analysis. Both sand and cake were tested for the same analytes as the bulk sediment, as listed in Table A-1.

Chemical Conditioning. Flocculants representative of anionic, nonionic and cationic polymers (Table A-2) were tested to ascertain whether any benefit in terms of filtrate quality or dewaterability would be obtained by conditioning the slurry prior to the dewatering step. Some of the slurry passing the 200-mesh sieve was further diluted to

approximately 7% solids by weight (80 g/L), representative of hydrocyclone overflow, for flocculent and dewatering testing. (The overflow slurry solids concentration was estimated based on an assumed dredge discharge concentration of 237 g/L solids. The dredge discharge concentration was based on an empirical relationship derived from field data: $C_{\text{solids}} = \% \text{Fines} + 3(\% \text{Sand})$ (personal communication Paul R. Schroeder June 2003²; Estes et al. in preparation) and assumes, for simplification, that 100% of the fines and the water would report with the cyclone overflow.) Preliminary flocculent testing was performed with 100 ml diluted fines slurry placed in a beaker, adding flocculent in drop-wise fashion and noting polymer volumes at which flocculation was observed. Polymers were added at 0.1% strength.

Those polymers producing good flocculation at lower dosages were further evaluated by a simple gravity drainage test. Polymer was added to 100 ml diluted fines slurry and the slurry was poured into a vacuum filtration apparatus fitted with a 90-mm Whatman 541 filter paper with 20-25 μm openings. The slurry was allowed to drain by gravity and recovered volume was recorded at intervals over the first 10 minutes. Vacuum was then applied and when no further drainage could be observed, final filtrate volume, turbidity and total suspended solids (TSS) were noted. The best flocculent and dosage was selected based on filtrate SS and gravity drainage rate.

² Paul R. Schroeder, P.E., PhD. Research Civil Engineer, Environmental Laboratory, ERDC Waterways Experiment Station, Vicksburg, MS.

Dewatering. A series of dewatering tests were performed using the diluted fines slurry. Testing was conducted with a 7.62 cm (3 in) bench top press manufactured by US Filter (Model 75N-1-MYHS). The press consists of a reservoir and filter chamber connected by high-pressure tubing, with a hydraulic ram to hold pressure on the assembly (Figure A-1). The system has a maximum operating pressure of 1551 kN/m² (225 psi). After filling with slurry, the reservoir is pressurized gradually, beginning at 172.4 kN/m² (25 psi) and increasing at uniform increments when filtrate flow slows to 2-4 cm³/min. Normal operating pressure is 689.5 kN/m² (100 psi) or higher. The test is usually terminated when flow slows to 2 cm³/min at highest pressure. (The termination flow rate corresponds to 0.41 L/min*m² (0.01 gpm/ft²), the typical termination point in full scale operation.) Gradually ramping up the pressure reportedly allows for better cake buildup, but is not a requirement for operation. Cycle times are not reduced by increasing pressure, however, according to the manufacturer.

The bench top press has a fixed volume chamber, which can be adjusted by installing different width chambers between the outer plates (Figure A-2). Using the 2.54 cm (1 in) chamber, a volume of 2L slurry at 7% solids by weight was needed to produce a full cake. A range of conditions was tested, including different filter cloths, polymer dosages, slurry volume and slurry solids concentrations. Some tests were also conducted including a fine sand fraction (+75 μ m -106 μ m) in the slurry, to evaluate improvement in dewaterability. Because the hydrocyclone separation does not produce a sharp cut, some sand will report with the fines to the dewatering circuit, and some fines will report to the sand fraction. The degree of carryover above and below the target cut size will be a function of the size and configuration of hydrocyclone used, solids concentration in the slurry, and throughput (Svarovsky 2000). Inclusion of sand in the fine slurry is therefore within the range of possible full scale process conditions.

Figure A-1
US Filter 7.62 cm Bench Top Press (Model 75N-1-MYHS), Reservoir, Chamber and Hydraulic Ram

Figure A-2
Variable Chamber, Filter Fabric and Ram

Several monofilament polypropylene filter cloths were provided with the press for testing, with measured air permeability ranging from 0.28 to 0.84 m³/s (10 to 30 cfs). Based on preliminary testing with the different cloths, the 0.28 m³/s cloth was selected for the final testing.

A series of 16 replicate tests were performed to produce sufficient sample for contaminant analysis. These tests used 1L undiluted fines slurry at 13.2% solids (147 g/l), with polymer dosage of 0.0408 mg/g and 0.28 m³/s cloth. (Undiluted slurry was used to minimize volume to be filtered.) Representative filter cakes were evaluated for remaining free water drainage using a paint filter test (Setup Figure A-3). Samples were also taken (in triplicate) from the filter cakes for measurement of percent moisture, percent solids and contaminants of concern (COCs). Filtrate was analyzed for TSS, turbidity and COCs.

Figure A-3
Paint Filter Test Setup

Results

Sediment Characterization. Grain size distribution of the combined sediment as measured by dry sieving and hydrometer is summarized in Table A-3. The only material >4.75 mm present consisted of debris, such as shell fragments, vegetation and plastic (Figure A-4). The combined sediment is characterized as 54% sand, with 46% fines. The sandy character of the sediment is apparent (Figure A-5). Little black carbon was visualized in any of the size fractions, but a coarse organic fraction appearing to consist of leaf litter and other natural material was present in the 500 μm to 4.75 mm size fraction. Particle size distribution as measured by coulter counter for the bulk sediment, sand and fines is illustrated in Figure A-6. Note that the sand fraction contains approximately 18 percent fines by volume, indicating some inefficiency in the sand separation. Similarly, the fines fraction contains about 8 percent sand size particles by volume. These may be irregularly shaped particles that passed through the sieve, but were measured by the Coulter as sand, or this fraction may consist of agglomerated fines that failed to break up in the sonication cell of the Coulter.

Table A-3
Grain Size Distribution

Homogenized, Combined, Bulk Sediment

Figure A-6
Particle Size Distribution as Measured by Coulter Counter for Size Fractions

Mean total dissolved solids in the pore water for the two sediments was 33.7 parts per thousand (ppt), determined gravimetrically. Salinity, as measured by a salinity meter (YSI Incorporated model 30/10 FT), was 33.1 ppt. Wet bulk density of the combined sediment was roughly estimated by obtaining the weight of a sample in a container of known volume, and verified using unit volume relationships and percent moisture. Geotechnical characteristics of the bulk sediment, sand fraction and dewatered cake are reported in Table A-4.

Table A-4
Geotechnical Characterization of Sand and Fines Fractions

Fraction	Sp. Gr.	Organic (%)	Wet Bulk Density (g/cm ³)	Total Solids (g/L)	Water Content (%)	Solids (%)
Bulk Sediment	2.7	4	1.66	1034.3	59.64	61.8
Sand	2.68	3.38	1.63	1184.5	47.4	67.1
Cake	2.72	4.6	1.76	1249.8	43.5	69.5

Chemical Analysis. Results of the chemical analysis conducted on the bulk sediment, sand, dewatered cake and filtrate are summarized in Table A-5. Mass balance on the contaminants in the sediment ranged from approximately 73 percent to 105 percent (Table A-5). Mass balance on the fractionated sediment resulted in an approximate recovery of 107.2% by weight. This is within the normal variation typically seen for fractionation studies.

Table A-5

a Total of 19 congeners. Assuming a concentration of 1/10 DL for non-detects, Total PCBs concentration would be 0.038 ug/l.

b Total of all aroclors. Assuming a concentration of 1/10 DL for non-detects, Total Aroclors and congeners would be 0.10 ug/l.

c Total of DDT and metabolites. Assuming a concentration of 1/10DL for non-detects, Total DDT concentration would be 0.02 ug/l.

d Detected in only one sample. Total concentration represents the mean of 0.025 and 1/10 DL (0.0025)

e Detected in only one sample. Total concentration represents the mean of 0.0022 mg/l and 1/10 DL (0.0001)

f TOC corrected for Soot and Oil and Grease

g Criterion applies to total PCBs (e.g. sum of all congener or all isomer or homolog or Aroclor analysis)

h Criterion applies to DDT and its metabolites (i.e. the total concentration of DDT and its metabolites should not exceed this value).

i Dissolved concentration.

Chemical Conditioning. Although saline sediments tend to flocculate and settle rapidly without chemical conditioning, gravity drainage of these sediments, as reflected by filtrate volume recovered, was enhanced with the addition of flocculent. Relative volumes obtained for a 10 min filtration period are illustrated in Figure A-7. Mean filtrate recovered for 17 tests was 21.5 ml, with a minimum of 13 ml, maximum of 23 ml, and standard deviation (SD) of 6.39 ml. Mean filtrate volume obtained for two unconditioned samples is also reported in this figure (14.5 ml). Highest volumes were recovered for MF368 at a dosage of 1 ml (0.128 mg/g). The improvement in volume recovery over the 0.3 ml (0.0384 mg/g) dosage was relatively small however (14 percent), as compared to the difference between the 0.1 (0.0128 mg/g) and 0.3 ml dosages (125 percent). The 0.3 ml dosage also resulted in a 21 percent higher volume recovery than the next best flocculent (MF10 at 0.3 ml/0.0384 mg/g). Total filtrate recovered after vacuum was applied varied less between tests, with a mean recovery of 93.5 ml, minimum of 88 ml, maximum of 96 ml and SD of 2.49 ml.

Figure A-7
Free (Gravity) Draining Filtrate Volume for Different Polymers and Dosages at 10 Minutes

Filtrate turbidity is illustrated in Figure A-8 by flocculent and dosage. Lowest turbidity was obtained with MF10 at 0.3 ml (6.69 NTU), but this was just slightly better than turbidity resulting for MF368 at 0.3 ml (7.6 NTU). Turbidity was higher for MF368 (9.62 NTU) at the 1.0

ml dosage (Figure A-4). TSS measurements were considered to be somewhat unreliable due to the low SS in the filtrate and sensitivity of the weight measurements to humidity changes and other influences.

Figure A-8
Gravity Filtrate Turbidity for Different Polymers and Dosages

Dewatering. Table A-6 summarizes the testing conditions utilized for the dewatering tests. Multiple tests were run in order to assess effects of different operating conditions and treatments, although the scope did not permit execution of a factorial to support statistical analysis of the results. Tests 7 through 22 were identical replicates, with the exception of test duration, run sequentially to produce sufficient cake and filtrate for chemical analysis. The system was pressurized in gradual increments, up to a maximum pressure of approximately 100 psi. Dewatering was continued until filtrate flow dropped below 2 ml/min at maximum pressure. Cycle time varied substantially between tests, ranging from roughly 3 hrs to 9 hrs. Although three different dosages of the flocculent MF368 were used in the dewatering testing, a dose of 0.0408 mg/g (MF368) was selected for the replicate mechanical dewatering tests (tests 7-22), with the intent that filtrate TSS and turbidity reflect best case filtrate quality.

Table A-6
Dewatering Test Conditions

Test No.	Polymer Dosage (mg/g)	Filter Fabric (m ³ /s)	Slurry Grain Size (μm)	Slurry TSS (%w/w)
1	0	0.84	<75	7.3

21	0.0408	0.28	<75	13.2
22	0.0408	0.28	<75	13.2

Flow Rates. Time required to complete each test varied. Flow rate was high initially for all tests, decreasing gradually to a relatively steady state flow (Figure A-9). The initial flow period was relatively consistent between tests (from time t=0 to time t=20 min, roughly). Mean effective flow rate for initial, established and overall flow is summarized by treatment in Table A-7. Because the testing was structured primarily to produce representative cake and filtrate, the data is not extensive enough to satisfy the requirements for formalized analysis of variance to assess effects of processing variables on flow rate. Based on the means obtained by treatment, however, overall flow rate was highest for unflocculated sediment, and coarse filter fabric (largely attributable to higher initial flow rate in both cases). Highest established flow rate was observed for the 2nd highest flocculent dosage however (0.0382 mg/g). Response of flow rate to differences in grain size and slurry suspended solids is more easily interpreted if dewatering test #1, the unflocculated test, is neglected. There was relatively little difference in the overall flow rate for the different grain size slurries. The lowest mean flow rate was

obtained for two of the three tests containing sand (approximately 1 ml/min lower than means for all other treatments), but standard deviation was also lowest for these two tests (Table A-7).

Filtrate quality. Both TSS and turbidity were measured in the filtrate. As expected, suspended solids releases during cake formation were noticeably higher for tests with no flocculent and for coarse weave filter fabric. Mean filtrate TSS and turbidity values reflect the effects of this initial SS release. Once a cake was formed, the filtrates all appeared (qualitatively) to be comparable with respect to filtrate SS. Table A-8 summarizes mean TSS and turbidity for the different treatments. Tests with the 2nd highest polymer dose, finest fabric weave, and finest grain size resulted in the lowest mean TSS and turbidity.

The relationship of TSS to turbidity can be useful for environmental monitoring of TSS in process discharges. TSS was correlated to turbidity for the combined sediments. The relationship may vary somewhat from that depicted in Figure A-10 for the individual sediments, but given their similarity, these results are expected to be reasonably representative.

Figure A-10
Filtrate TSS versus Turbidity for Combined Sediment

Dissolved contaminant concentrations were below detection in the filtrate for all PCBs, pesticides and silver (Table A-5). Total silver concentration was non-detect in one filtrate sample and approximately twice the detection limit of 0.001 mg/l in the other sample. Mean total silver concentration in the filtrate (assuming a concentration of 1/10 the DL for the non-detect sample) is 0.0012 mg/l (1.2 ug/l), which is below the federal marine acute water quality standard of 1.9 ug/l for dissolved silver. No numerical criteria were available for TOC, DOC and oil and grease for sediment or surface water.

Cake Percent Moisture/Percent Solids. All cakes tested (5 of 22) passed the paint filter test (Figure A-11). Percent solids ranged from 56 percent to 78 percent; with a mean of 69 percent for all 22 dewatering tests, and a mean of 69.5 percent for the 16 replicate tests. Percent moisture ranged from 22 percent to 44 percent; with a mean of 30 percent for all 22 dewatering tests and for the 16 replicate tests. Mean percent moisture and percent solids are listed by treatment in Table A-9. Variation in percent moisture and percent solids with time and pressure are illustrated in Figures A-12 and A-13. No clear trends in percent solids are evident for time and pressure variables and neither variable was significant in simple linear regression against percent solids for the replicate tests. Effects interactions overall could not be evaluated using ANOVA due to the unbalanced nature of the testing design and the number of missing values resulting in the matrix. Also, effects due to slurry TSS and time are interdependent, because slurry volumes were higher for more dilute slurries thus increasing the amount of time required to filter the slurry. Although variation in percent solids for different values of the independent variables (Table A-9) do not appear to be large enough to be of practical

significance, a balanced matrix would be helpful in subsequent testing to further evaluate optimum operating conditions. The results obtained in this testing could be used to refine a factorial test to address specific questions of operational significance.

Figure A-11

a <106 μm slurry

Figure A-12
Filter Cake Percent Solids by Pressure and Time

Figure A-13
Filter Cake Percent Moisture by Pressure and Time

Cycle Time - Total cycle time for Tests 7 through 22 (the replicate tests) ranged from 185 min to 530 min. There appeared to be no correspondence between operating pressure (the only variable that was not well controlled for the replicate tests) and cycle time. Cycle time over all tests was longer for more dilute slurries due to the higher volume of slurry required to produce enough solids to fill the press chamber.

DISCUSSION AND ANALYSIS

Fractionation and grain size analysis of the sediment indicates that two size separations will be required in order to recover the sand fraction. The oversize material (>4.75 mm) consists largely of leaf litter, shell fragments and other debris, which can likely be removed successfully with a scalping screen. There was no gravel present in the sample sediments. Hydrocyclones have been proposed for separation of the undersize material (<75 μm), although alternative processes may also be considered.

For these sediments, on the basis of the laboratory testing, there is not a clear distribution of contaminant between fine and coarse materials. Concentrations of some contaminants in the sediment could be problematic to beneficial use of the materials. Total Aroclor concentrations in the bulk sediment, sand and cake all exceeded the ER-L, but were below the ER-M. PPDDT concentrations were non-detect in the bulk sediment and fractions, but the detection limit exceeded the ER-L slightly, so a definitive determination with respect to the ER-L cannot be made on the basis of this data. Detection limits for PPDDT were below the ER-M, however, indicating that sediment concentrations are also below the ER-M. Concentrations of the metabolites PPDDD and PPDDE were above the ER-L but below the ER-M in bulk sediment and fractions. Silver concentrations were below the ER-L in all sediment fractions.

As phases with high affinity for organic contaminants, TOC, soot and oil and grease distribution typically correspond to contaminant distribution, although this is difficult to demonstrate statistically with a small number of samples. TOC and soot concentrations were comparable in the sand fraction and in the dewatered cake, which may partially explain the contaminant distribution. Oil and grease was slightly higher in the sand than in the cake, but this may be an artifact of the wet sieving process, where free oil and grease floating on the water may have settled onto the sand fraction rather than passing through the sieve. In hydrocyclone separation, free oil and grease would be expected to report to the overflow with the fine sediments and low-density materials. Coarse but light organic materials, such as the leaf litter present in the sand fraction, may also report in greater proportion to the overflow. The sand

fraction produced by the hydrocyclone separation therefore has the potential to be less contaminated than the sand fraction obtained by wet sieving. In this case, however, some fines remained in the sand fraction, which likely contributed to the contaminant loading in the sand fraction and which may also be fairly representative of the particle distribution that would be obtained with a hydrocyclone. Any reduction in contaminant concentrations in the sand that would be obtained with a cyclone would then come primarily from a greater proportion of the oil and grease and light organic materials reporting with the fines. (A wet screen, on the other hand, would not be expected to be a good equipment choice for the primary sand separation as the coarse organic materials, and possibly also the oil and grease, would report with the sand in much the same manner as in the bench scale wet sieving.)

Hydrocyclones do not produce a sharp cut, instead producing a distribution of particle sizes around the specified cut size. A percentage of the fine material (the percentage decreasing with decreasing particle size) will report with the sand in the underflow. Similarly, a percentage of the sand (the percentage decreasing with increasing particle size), will report with the fines in the overflow. The relative proportions of fines reporting with the sand, for example, will be determined by the size of the hydrocyclone, the configuration and the operating conditions. More dilute slurries facilitate more complete separation in the hydrocyclone. Larger cyclones (typically >12 in nominal diameter) are most suitable to achieve a cut size at or above 75 μm . Various modifications to the cyclone construction, such as the maximum density separator (Granat 1998) are available to improve the efficiency of separation and may best be evaluated in pilot testing. Hydrocyclones can be installed in parallel, providing a high degree of flexibility with respect to capacity. Both slurry pumps and hydrocyclones will require abrasion resistant construction if used as the principal sand separation step.

The dewatered (fine) residuals volume (V_{Tf}) can be calculated based on initial in-situ bulk sediment volume (V_{ti}), and measurable properties of the materials before and after separation and dewatering. The relationship is given by the following expression (Olin-Estes et al 2002):

Where: $V_{Tf} = bV_{Ti}$

And:

$$b = \frac{(1+w_f)[(1-x_m)M_{Si} + M_{Fi}]\rho_{ti}}{(1+w_i)(M_{Si} + M_{Fi})\rho_{tf}}$$

b	= volume reduction factor
Q_{ti}	= total or wet density, in-situ or initial
Q_{tf}	= total or wet density, final
w_i and w_f	= water content, as a decimal
M_{Si}	= mass sand, in-situ or initial
M_{Fi}	= mass fines, in-situ or initial
x_m	= sand removal efficiency

The relative volumes of sand and dewatered cake produced for varying efficiencies of sand recovery are illustrated in Figure A-14. The values obtained are based on the assumption that total (wet) density and water content measured in the cake composed of $< 75\mu\text{m}$ particles are representative of cake containing increasing proportions of sand particles. Some variation of density and final water content would be expected for different cake composition, but available data was too limited to extrapolate values. A 10% reduction in final water content results in a 3% reduction in final residuals volume (assuming a saturated cake). A 20% reduction in water content results in an 8% reduction in final residuals volume. Assuming the measured water content and wet density of the fine cake would not vary by more than 10% from the values obtained here, the estimated residuals volumes should be reasonably representative for planning purposes. A void ratio of 0.9 was assumed in calculating final volume for the separated sand fraction.

Figure A-14
Relative Volumes of Sand and Dewatered Residuals as a Function of Sand Separation Efficiency (with efficiency defined as the fraction of sand present in bulk sediment that reports to the sand fraction)

Given the similarity of contaminant concentrations in sand and fine fractions as produced by wet sieving, inclusion of a small percentage of fines in the sand would not be expected to increase contaminant concentrations significantly with the exception of silver, which was an order of magnitude higher in the cake than in the sand. Distribution of silver for different proportions of sand and fines is illustrated in Figure A-15. Values in Figure A-15 were obtained by assuming all of the sand and a specified portion of the fines were combined, or that all of the fines and a specified portion of the sand were combined. In actual processing, each process stream will contain both fines and sand, with one or the other in greater proportions. Cyclone underflow (operationally defined sand fraction) might contain as much as 10-20% fines by weight. Similarly, the overflow might contain a similar proportion of sand. The values in Figure A-15 then illustrate the trends expected with varying proportions of either fraction. Concentrations for the sand fraction containing a representative range of percent fines (for hydrocyclone separation) are illustrated Figure A-16.

Figure A-15
Silver Concentration in Sand and Cake as a Function of Relative Sand/Fine Composition

Figure A-16
Ag Concentration in Sand Fraction for Representative Percent Fines in Sand

Flocculent addition did appear to improve sediment dewaterability, as measured by volume of free draining fluid released in gravity filtration tests, and filtrate quality as reflected by turbidity and TSS. One coagulant (MF368) was clearly superior to the others tested with respect to volume filtrate recovered by gravity, and was second only to MF10 with respect to filtrate turbidity. The difference in free draining volume obtained at the optimum dose of MF368 (0.128 mg/g) compared to that obtained with a dose of 0.038 mg/g (which was optimum for turbidity), was relatively small (about 14%). Given that nearly equivalent volume was obtained for all tests once pressure was applied (although different times were required to complete filtration), the higher dosage of MF368 did not appear to be justified. The lower dosage of MF368 also produced the highest steady state flow rates in the press. Because chemical conditioning can be relatively expensive, utilization of a lower dose could result in substantial cost savings.

In the press, percent moisture of the cake was fairly uniform for all flocculants and dosages tested. Additionally, once a cake was formed, flow rate was fairly comparable for both fabrics tested and both grain size distributions, with or without flocculent. Flocculent addition did reduce initial filtrate SS over that obtained for the unflocculated test, and for tests using coarse filter fabric. As for filtration rate, however, once the cake was formed, SS appeared to be almost equivalent. Filtrate recycling through the press would be a viable alternative to chemical conditioning for reduction of high initial filtrate SS levels. If filtrate were to be used for offloading of mechanically dredged materials, this would be an integral part of the process, and

would not increase the volume of water being processed through the press (which would otherwise increase cycle times and possibly offset any cost savings realized by eliminating chemical conditioning). Processing of more dilute slurry has a similar effect, requiring more fluid to be pumped through the press, increasing cycle times. Pre-thickening the cyclone overflow slurry would therefore be desirable and would help to minimize variation in the solids content of the press feed.

Cake quality was relatively uniform for all tests, regardless of cycle time, chemical conditioning, pressure variations, and slurry grain size and percent solids. Trends with respect to longer processing time and higher pressure were not clear, although there was some indication that very high pressure and very long treatment times may produce cake with higher percent solids. The practical value of the incremental improvement in cake quality is likely to be offset, however, by increased operating costs and cycle times. Optimization focused on measures to reduce cycle time is likely to be most beneficial. Pre-thickening feed to minimize filtrate volume and flocculent addition to produce a low SS filtrate would reduce cycle times and minimize water treatment costs. Mean final water content for the replicate dewatering tests was 43.5 percent, which results in an estimated .41 m³ dewatered residuals volume per m³ in-situ sediment processed. Variation in dewatered residuals volume with varying final water content (assuming saturated cake) is illustrated in Figure A-17. (Figure A-17 assumes a representative 92 percent of fines reporting to the fine fraction along with 15 percent of the sand by weight.)

Figure A-17
 Dewatered Residuals Volume Variation for 10 Percent Variation in Final Water Content
 (for a unit volume of sediment and fixed sand separation efficiency)

Filtration Theory

Based on the bench testing with the filter press, the compressibility and characteristic flow resistance were evaluated using the filtration equations given by Tenney (1972):

$$\frac{dV}{dt} = \frac{PA^2}{\mu(rcV + R_m A)} \quad (1)$$

Where:

V	= volume of filtrate (cm ³)
t	= time (s)
P	= vacuum, (g/cm ²)
A	= filtration area (cm ²)
μ	= filtrate viscosity (poise)
r	= specific resistance of the cake (s ² /g)
c	= weight of solids per unit volume filtrate (g/cm ³)
R _m	= initial resistance of filter media (s ² /cm ²)

Rearranging gives:

$$\frac{t}{V} = \left(\frac{\mu rc}{2PA^2} \right) V + \frac{\mu R_m}{PA} \quad (2)$$

Plotting t/V versus V one can solve for specific resistance:

$$r = \left(\frac{2PA^2}{\mu c} \right) b \quad (3)$$

Where b is the slope of the t/V versus V plot (Equation 2).

Plots of t/V versus V for all of the duplicate dewatering tests (tests 7-22) were generated, giving a mean specific resistance value of 6.51E08 s²/g based on the mean slope of 0.046 s/cm⁶ for the tests and mean values for the other parameters: P = 7581.4 g/cm² (107.81 lb/in²), A = 40.53 cm² (two times the individual plate areas), μ = 0.01072 poise, c = 0.163 g/cm³ (c was calculated using initial and final moisture content of slurry and cake, respectively, according to the relationship given in Equation 19-4, in Tenney (1972)). The specific resistance was used in calculating a loading factor, from which filter area can be estimated. The loading factor (L) is given by Tenney (1972) as:

$$L = 35.7 \left[\frac{cP^{(1-s)}}{\mu t_c R_1} \right]^{1/2} \quad (5)$$

Where

- t_c = total cycle time (min)
- R_1 = mean specific cake resistance ($\text{rx}10^{-7}$)
- s = cake compressibility (unitless)
- P = pressure (psi)
- L = loading factor ($\text{lb/ft}^2 \text{ hr}$)
- μ = filtrate viscosity (centipoises)
- c = weight solids per unit volume filtrate (g/cm^3)

To calculate L , characteristic values are needed for compressibility (s) and for cycle time (t_c). For compressible cakes, the average specific cake resistance is time dependent, increasing as the cake becomes progressively more consolidated. Because the variation in pressure between tests for the current study was very limited, it was not possible to determine the compressibility of the material with a high degree of certainty. Typical values for cake compressibility (s) range from 0.1-0.8. The organic content of the sediment was low (4.6% by weight in the fine fraction) suggesting that the sediment should not be highly compressible. However, the relationship of flow to pressure for the study sediments was consistent with behavior associated with compressible sediments (flow rate did not increase with increasing pressure). A range of loading factors were therefore calculated to assess the impact of this factor.

Cycle termination (the point at which filtrate flow diminished to 2ml/min) was difficult to determine given the long duration of some of the tests and the low flow rates. A representative time at which 95% of the total filtrate volume had been passed was obtained from regression on plots of filtrate volume versus time for the replicated dewatering tests. The representative cycle time was calculated from the fitted equation (best fit was obtained for either a logarithmic or power function) resulting in cycle times ranging from 2.2 to 12.7 hours. A loading factor was then calculated for each test, assuming the following values for the remainder of the parameters:

- R = $1.24 \text{ s}^2/\text{g}$
- c = 0.163 g/cm^3
- P = 7581.4 g/cm^2 (107.8 psi)
- t_c = 300 min (5 hours)
- μ = 1.072 centipoises
- s = 0.1 – 0.8

For the given range of s , the mean loading factor ranges from 0.850 kg/m²hr to 4.38 kg/m²hr (0.174 lb/ft²hr to 0.897 lb/ft²hr). The filter area needed was then estimated based on daily dredge production. The production rate for a 6" dredge is approximately 0.148 m³/s (5.24 ft³/s). For the given grain size distribution, assuming 20 hours/day operation of the dredge, 1.02E06 kg of fine solids would be produced daily. For the given range of loading rates, filter area required would range from approximately 1.26E4 m² to 6.47E4 m² (1.36E05 ft² to 6.96E5 ft²), increasing exponentially with increase in compressibility (Figure A-18). Given the importance of this factor, this approach requires considerable certainty regarding the compressibility of the sediment. In addition, these values seem unreasonably high when compared to an intuitive analysis of the filtration volume required based on the daily solids production, the wet bulk density of the cake, the daily dredging and dewatering periods, cycle time and press volume. These relationships are obtained directly from the test results, and are independent of the compressibility factor, which is accounted for implicitly in the filter loading obtained. The number of filters required for a 24 hour dewatering operation supporting a 6-in dredge was estimated for different daily dredging periods, assuming 5.78 cycles could be completed in 24 hours of operation (based on mean cycle time for batch testing), 6.2 m³ (219 ft³) cake capacity per press, and 0.865 kg/m³ (0.054 lb/ft³) wet cake density (based on mean value for batch testing). The total number of presses required ranges from 6 to 29, for a 4 to 20 hour dredging period per day, respectively. Plant capacity required for other dredging periods is given in Table A-10. No factor of safety was applied to these values, but a factor of safety as high as 25% is recommended in Perry et al (1984).

Table A-10
Press Capacity versus Dredging Period¹

Dredge Operation hrs/day	Total Press Volume m³ (ft³)	No. Presses
20	184.5 (6516)	29
18	158.5 (5595)	26
16	140.8 (4973)	23
14	123.2 (4351)	20
12	105.6 (3730)	17
10	88.1 (3108)	15
8	70.4 (2486)	12
6	52.8 (1865)	9
4	35.2 (1243)	6

¹6-in dredge, 0.095 m³/s (3.34 ft³/s) fine slurry dredge discharge, 6.2 m³ (219 ft³) cake capacity per press, 24 hour dewatering operation, 5.78 dewatering cycles/24 hours

Figure A-18
Filter Area Required Versus Compressibility Factor(s)

The optimum cycle time is another factor deserving further evaluation. The most efficient filtrate production occurs over the first part of the cycle, while the most efficient solids capture occurs after a cake has accumulated and flow rates have diminished. There may be a transition point at which the flow rate clearly diminishes to the point that continued operation is not efficient. If it exists, this transition point can be identified in plots of flow rate versus filtrate volume. There was no clear transition point in plots for the study sediments. An alternative approach was therefore taken, in which the optimum cycle time was estimated based on solids flow rate. It was apparent from the measured dry mass of solids reporting to the cake relative to the corresponding filtrate volume that some settling of solids occurred in the system upstream of the filter, in effect reducing the feed slurry concentration. Taking the effective feed solids concentration to be equal to the mass solids on the filter divided by the total filtrate volume (having a mean value 93 g/L), and using the measured filtrate flow to calculate a solids flow rate, the majority of the solids were delivered in a period ranging from as little as 3 hrs to about 6 hrs (Figure A-19). Based on the regression line from all the filtration data, 95% of the solids were delivered in about 4.6 hrs. Continued operation after this point appears to add little to the cake mass. This reduces the number of presses required, based on the previously stated assumptions, to a minimum of 5 and maximum of 26 presses.

Figure A-19
Filter Solids Loading Versus Time

One of the difficulties of scaling up from the bench scale results, however, is that the operating regimes may differ significantly. In a full scale system using positive displacement pumps and a constant flow regime, feed to the press would be expected to be consistent over the entire cycle. Longer cycle times would presumably correlate to higher solids in the cake, and cycle termination would be determined when a maximum acceptable pressure drop across the system was reached. For a variable feed, variable pressure system fed with centrifugal pumps, the regime would be more similar to the bench testing, and the diminishing rate of solids transfer would need to be taken into consideration in determining optimum cycle time. Ultimately, while bench scale testing is useful in defining parameter ranges and assessing overall feasibility, pilot scale testing is probably a requirement in order to assess the effect of parameter variations in a more representative operating regime. For the study sediments, based on the bench scale testing, we can conclude that the press volume required to dewater the sediment with a plate and frame press is sufficiently high that the dredging operation would be constrained to a small dredge operating for limited periods each day.

Conclusions

Optimizing the separation and dewatering process requires clear definition of the processing objectives and the parameters that will be used to gauge success. Where off-site disposal of dewatered material is a requirement, as in this case, minimizing volume and weight of the cake is desirable in order to minimize transportation costs and tipping fees. Potential cost benefits must be weighed against costs incurred to minimize water content and cake volume in order to attain lowest overall project costs. Highest efficiency is not always least cost overall when all factors are taken into consideration. Because dewaterability did not appear to be strongly improved by inclusion of sand in the cake, and the incremental mass reporting to the cake was relatively large for this sediment due to the amount of sand in the fine sand fraction, sand inclusion should be considered as incidental to the process, but not a processing objective. It is possible that an additional screening step between the cyclone and the filter press would be desirable to recover fine sands reporting with the overflow, in order to further minimize cake volume and weight.

Processing trade-offs are expected to be more critical when different dewatering processes are being compared. For plate and frame dewatering, differences in volume and cake for a reasonable variation in operating parameters do not appear to be large enough to capitalize upon, with the exception of removing as much sand as possible before the dewatering step.

One aspect of treatment that is clearly related to the economics of the process is cycle time. The longer the cycle time required to achieve dewatering objectives, the larger the dewatering plant must be in order to accommodate a given dredge production rate. It is also apparent that the more dilute the slurry is, the larger the volume of water that must be processed by the system and the greater the volume of water requiring management and possibly treatment prior to discharge. Thickening of the influent slurry prior to the dewatering step would appear to be beneficial in reducing hydraulic loading and cycle time. Cycle times varied considerably and were relatively long for these sediments. This was partly a function of the testing protocol, which required operating the press until filtrate flow fell below a prescribed level. Because some solids settled out in the system, solids flow rate appears to have been lower than that calculated from the initial slurry concentration. In practice, depending upon the system configuration, and assuming consistent slurry solids concentration in the feed, somewhat shorter cycle times should be attainable.

Based on the cycle times required for the bench scale testing, multiple presses would be required at full scale to accommodate the discharge from even a small (6-inch) dredge. In

addition, dredge operation would likely have to be intermittent, while the dewatering operation would need to be continuous. Filter volume requirements for a larger dredge would appear to be completely infeasible.

Concentrations of several contaminants in the bulk sediment and fractions fell between the ER-L and ER-M, including Total Aroclors, PPDDD and PPDDE. With the exception of silver (Ag), contaminant concentrations were not substantially reduced in the sand as compared to the fine residuals. Silver was below the ER-L in all sediment fractions. Improved separation of coarse organic materials and oil and grease might reduce sand concentrations further, but this would have to be confirmed with more extensive and definitive bench scale testing or representative full scale separation equipment.

Contaminant concentrations in filtrate were below detection for PCBs, pesticides and dissolved silver, although the detection limit for Total Aroclors, PPDDT and Total DDT were above the federal marine chronic criteria so no definitive conclusions can be drawn. Total silver was approximately twice the detection limit in one filtrate sample and non-detect in the other. The resulting mean concentration is still below the federal water quality criteria for dissolved silver indicating there should be no exceedances of this criteria. TSS and turbidity in filtrate from unflocculated sediments was 5 to 25 times higher than in filtrate from flocculated tests. This is largely attributable to solids losses early in the dewatering cycle, and could likely be addressed by recycle of affected filtrate. In the absence of numerical criteria for TSS and turbidity, receiving water quality would in part determine acceptability of filtrate for discharge with respect to these two parameters.

APPENDIX B
HYDROCYCLONE SAND SEPARATION LABORATORY BENCH-SCALE
STUDY

Hydrocyclone Sand Separation Laboratory Bench-Scale Study (Tri-Flo International)

Objective

To test the efficiency of using a hydrocyclone unit to separate the sand and fine-grained sediment fractions from representative contaminated dredge material as a means of recovering a beneficial use product (sand) and minimizing disposal volumes (fines).

Background

The Los Angeles District Corps of Engineers is interested in identifying methods for treating contaminated sediments generated during federal maintenance dredging projects within the Los Angeles Basin. One method under consideration is the concept of sand separation as a mechanism for reducing contaminant concentrations and producing a reusable by-product (clean sand) for regional beach nourishment. This laboratory bench-scale study was conducted to gather data to assist in evaluating the feasibility of this approach for use in a regional contaminated dredge material treatment facility.

The concept for this treatment approach lies in the assumption that most contaminants are tightly bound to the fine-grained and organic fractions of the sediment and not strongly associated with the courser sand fractions. Therefore, if a mechanical process were available to effectively separate the coarse sand fraction from the fine-grained and organic material, it should be possible to concentrate the contaminants into a de-watered, fine-grained cake for disposal and produce “clean” water and sand as re-useable by-products.

One commercially available method for mechanically separating the sand from the fine-grained fractions is to use a hydrocyclone. Hydrocyclones are large conical shaped devices that produce a vortex of the sediment slurry which allows the heavier sand fractions to migrate to the outside of the cone and drop out in the underflow while the less dense, finer-grained fractions are carried to the center of the cone and flow out the top as the overflow. This fine-grained slurry (overflow) can then be transferred to a second piece of equipment (e.g., belt press) and dewatered to produce a dry cake with the wastewater either being reused for additional dredge slurry or discharged back to the sample location.

Test Material

Contaminated test sediments were collected from two locations in Southern California (the Los Angeles River Estuary (LARE) in Long Beach and the Rhine Channel in Newport Bay) using

conventional field coring methods. Both samples were representative of typical Corps dredging areas and both are known to contain elevated concentrations of metals, PAHs, pesticides, and PCBs, which precludes them from being disposed of at an unconfined ocean disposal site. Approximately 8 gallons of sediment were collected from the Rhine Channel location and approximately 5 gallons were collected from the LARE location.

Sand Separation Test Equipment

This bench-scale study was conducted at the offices of Tri-Flo International, Inc located in Willis, Texas using a 4" hydrocyclone unit capable of 30 GPM flow and producing a cut size of 30-35 micron sand particles (Figures B-1 and B-2).

Figure B-1
Tri-Flo International 4" Mobile Hydrocyclone Unit

Figure B-2
Tri-Flow International View of 4" Hydrocyclones

Study Design

The intended study design for the laboratory bench-scale study included the following steps for each sediment sample:

1. Homogenize sediment sample in collection bucket(s) to achieve a uniform sample, removing large pieces of debris in the process.
2. Prepare seawater diluent using artificial sea salts to a salinity of 28-30 ppt.
3. Mix sediment and seawater in large plastic mixing tanks or trash cans to achieve a 10-20% solids suspension.
4. Feed sediment slurry into hydrocyclone – output will be dewatered sand and fine-grained slurry.
5. Collect sample of sand and slurry for chemical and physical analyses.
6. Allow remaining slurry to settle and then filter using a 0.45 micron in-line filter to produce a filtered water sample for dissolved chemical analysis.
7. Prepare and package all samples for shipping

This process is illustrated graphically below in Figure B-3, and the targeted samples are summarized in Table B-1.

Figure B-3
Hydrocyclone Bench-Scale Study Process Diagram

Table B-1
Target Chemical and Physical Analyses

Sample	Chemical Analyses	Physical Analyses
T ₀ Bulk Sediment Sample	Metals, PAHs, PCBs and Pesticides (1/site = 2 total)	Grain Size, %Solids (1/site = 2 total)
T _F De-watered Sand Fraction	Metals, PAHs, PCBs and Pesticides (1/site = 2 total)	Grain Size, %Solids (1/site = 2 total)
T _F Dewatered Fine-Grained Solids	Metals, PAHs, PCBs and Pesticides (1/site = 2 total)	Grain Size, %Solids (1/site = 2 total)
Filtered Wastewater	Metals, PAHs, PCBs and Pesticides (1/site = 2 total)	DOC (1/site = 2 total)

Totals = 6 sediment samples for chemical and physical analyses
 = 2 water samples for chemical analyses and DOC

Study Results

Due to time constraints at the test facility, only one sample was ultimately exposed to the hydrocyclone system. Although it contained a lower sand fraction, the Rhine Channel sample was selected for use because it had a much higher, and robust, contaminant load.

Contaminants present included metals, PAHs, pesticides and PCBs; all at concentrations above typical aquatic screening level threshold values.

A total of two 5-gallon buckets of material were collected from the Rhine Channel. One sample was collected from an area with very high metal and organic concentrations (Station 16) and another from an area with similar metal, but lower organic chemical concentrations. The material from both buckets were homogenized together and then diluted with 176 gallons of synthetic seawater to a salinity of 28-30 ppt. Unfortunately, the “bulk sediment” sample collected to represent the starting material concentrations was inadvertently collected from the bucket containing the samples with the lower organic chemical concentrations and not from the homogenized mixture. The effects of this event are discussed later in this report.

After processing, samples were collected from the washed sand (“Rhine Sand”) and the fine-grained slurry was placed into a HDPE bucket for settling. Visually, the sand material was dry and free of organic material (Figure B-4). The fine-grained slurry passing through the 4” hydrocyclone was allowed to settle for approximately two hours, at which time the overlying water was siphoned off and passed through a 0.45 micro pre-washed filter directly into a sample collection bottle (“Rhine Decant”). The remaining sediment in the bucket (fine-grained fraction, termed “Rhine Cake”) was then collected for chemical analysis. All samples were packed on wet ice and shipped via overnight courier to CRG Laboratories in Torrance, CA for testing. Test results are presented in Tables B-2, B-3, and B-4.

Table B-2 presents the results of the metals analyses conducted on the bulk sediment, sand fraction, decant water and dewatered fine-grained cake. Overall, the process was quite effective in reducing bulk sediment metal concentrations. With the exception of cadmium, nearly all metals were reduced by up to 80% of their initial concentration. To account for the errors in collecting the bulk sediment sample prior to treatment mentioned above, both the average bulk concentration (average of three replicates) and the data solely for Station 16 are presented in the tables to show the range of reductions that may have occurred. Because the metal concentrations at the two Rhine Channel collection points were very similar, both comparisons show similar results.

Results from the process water showed that the metals were concentrated in the fine-grained cake and that partitioning into the dissolved phase of the overlying water did not occur as these values were all very low (using EPA's chronic marine ambient water quality criteria as a reference point).

Bulk sediment pesticide and PCB concentrations between the two Rhine Channel source samples were quite different, with the results for Station 16 being one or more orders of magnitude higher than other station. This caused the evaluation of chemical reduction (see Tables B-3 and B-4) to actually show erroneous negative values suggesting that concentrations increased following treatment. However, when evaluating the data against the bulk sediment concentrations for Station 16 by itself, the tables show significant reductions for almost all organic contaminants. Most notably were the PCBs which were reduced by 82 percent to 95 percent after treatment.

APPENDIX C
HYDROCYCLONE SAND SEPARATION FIELD PILOT STUDY

Hydrocyclone Sand Separation Field Pilot Study (Tri-Flo International)

Objective

The purpose of this field pilot study was to validate the results of the laboratory bench scale hydrocyclone sand separation study (Appendix B) using full-scale, commercially available, equipment outfitted with larger cone sizes for larger sand fraction recovery.

Background

The Los Angeles District Corps of Engineers (USACE) is interested in identifying methods for treating contaminated sediments generated during federal maintenance dredging projects within the Los Angeles Basin. One method under consideration is the concept of sand separation as a mechanism for reducing contaminant concentrations and producing a reusable by-product (clean sand) for regional beach nourishment. A laboratory bench-scale study was conducted to gather data to assist in evaluating the feasibility of this approach for use in a regional contaminated dredge material treatment facility (Appendix B). The results of that bench scale study showed that the approach was effective in reducing contaminant concentrations for both metals and organics, but it needed to be field tested. The current study was designed to meet that need.

The concept for this treatment approach lies in the assumption that most contaminants are tightly bound to the fine-grained and organic fractions of the sediment and not strongly associated with the courser sand fractions. Therefore, if a mechanical process were available to effectively separate the course sand fraction from the fine-grained and organic material, it should be possible to concentrate the contaminants into a de-watered, fine-grained cake for disposal and produce “clean” water and sand as re-useable by-products.

One commercially available method for mechanically separating the sand from the fine-grained fractions is to use a hydrocyclone. Hydrocyclones are large conical shaped devices that produce a vortex of the sediment slurry which allows the heavier sand fractions to migrate to the outside of the cone and drop out in the underflow while the less dense, finer-grained fractions are carried to the center of the cone and flow out the top as the overflow. This fine-grained slurry

(overflow) can then be transferred to a second piece of equipment (e.g., belt press) and dewatered to produce a dry cake with the wastewater either being reused for additional dredge slurry or discharged back to the sample location. A preliminary bench-scale study was conducted to test the technology using a 4-inch hydrocyclone to produce a sand cut size of approximately 35 microns. While substantial reductions in contaminant concentrations were achieved for this size fraction, the goal of the technology is to produce beach compatible material which typically has larger grain sizes than 35 microns.

Since larger cut sizes using hydrocyclones are achieved by using a larger cone size in the system, a field pilot study was initiated to use a 10-inch cone capable of producing a cut at approximately 75 microns which would be more representative for beach nourishment. This technical appendix presents the results of that full-scale field pilot study.

Test Material

The test material for the field pilot study was sediment dredged in June 2005 from the mouth of the Los Angeles River, just upstream of the Queensway Bridge, as part of an emergency dredging effort to restore navigation depths to the entrance channel for the Catalina Cruises Ferry Terminal. Approximately 800 cubic yards of sediment were dredged by Manson Construction using a clamshell bucket and placed onto a flat deck barge containing “K” rails to prevent the material from sloughing off back into the water. Bulk sediment chemistry for the dredge material is presented in Table C-1, and shows elevated concentrations for both metals and organics. Two sources of bulk sediment chemistry data are available: (1) results from the pre-dredge characterization which are labeled as “Area 1-2 top and bottom”, and (2) results from samples collected after stockpiling it on the flat deck barge just prior to processing. These latter samples were collected from two areas of the barge, one area contained sediment with a high sand content and one area contained sediment with high silt/clay content. This was done to provide a range of potential analytical results as the LARE area is typically variable with respect to grain size and chemical composition.

Study Design & Equipment

Due to some logistical constraints related to obtaining access to a suitable upland location for conducting the pilot study, the actual program was conducted entirely on barges anchored at the mouth of the Los Angeles River near the entrance to the Shoreline Marina. The treatment

design for the study is presented schematically in Figure C-1 and the barge layout is shown in Figure C-2. The treatment process included the following key steps:

- Prepare dredge material slurry using bulk sediment and site water to a target suspension of 10-15% solids;
- Pass the material through a scalper (shaker) screen to remove trash and debris;
- Pass the remaining material through a 10" hydrocyclone to remove all material above 75 microns;
- Pass the remaining material through a bank of 4" hydrocyclones to remove the material between 35 and 75 microns;
- Transfer the residual slurry to settling tanks to allow some of the remaining particulates to drop out; and
- Reroute settled slurry water back to slurry tank to mix with new bulk material or allow continuing settling and then decanting clarified water back to dredge site.
- Dispose all trash and woody debris from the scalper screen, along with residual solids from the settling tanks, at landfill or suitable port disposal area.

Figures C-3 through C-10 contains photographs of the actual test equipment and barge layout. The City of Long Beach paid for the sediment dredging and the USACE funded the actual costs of the field study and analytical testing program. Field equipment used for this study was provided by the following:

- Manson Construction – prime contractor and project management, derrick barge, field crew, generator, slurry tank, Baker tanks and settling tanks
- Tri-Flo International – hydrocyclones, pumps, and field crew
- Connolly Pacific – flat deck barges

Sand Separation Test Results

Chemical results for the bulk sediment and processed sand are summarized, by day, in Table C-1 and presented graphically in Figures C-11 through C-18. Sample designations include "debris" for the organic matter and trash removed by the scalper; "CS" for course sand which consists of the cut material produced by the 10" hydrocyclone; and "FS" for the fine sand cut from the 4" hydrocyclones. Table C-2 presents a log of all sediment samples collected during the study, along with a description of any treatment process modifications made prior to or after sample collection.

Figure C-11 presents the inorganic results of six metals (mercury, copper, lead, cadmium, zinc and nickel) measured in mg/kg. Three samples are labeled as Bulk (Bulk Weight), CS (Coarse Sand), and FS (Fine Sand). Four samples were taken for the bulk weight, with the dark purple bar denoting the average concentration and six samples were taken for both the CS and FS over the 4 day duration of processing. Overall, CS and FS samples showed decreasing trends in inorganic concentrations from the bulk material suggesting that the process was effective in reducing metal concentrations.

For mercury, bulk sediment concentrations ranged from 0.01 to 0.17 mg/kg and averaged 0.09 mg/kg. With the exception of one CS sample, all post processed samples showed significant reductions after passing through the hydrocyclones. The CS samples were lower than the FS samples suggesting that some carry-over was occurring at a partial size fraction between 35 and 75 microns, the cut sizes for the 4" and 10" hydrocyclones, respectively. Similar results were observed for copper, lead, cadmium, nickel, and zinc. Occasional post-processed samples produced concentrations above that observed for the bulk samples which suggest variable concentrations and equipment efficiencies. In all cases, however, CS concentrations were lower than FS concentrations. As with the mercury results, this suggests that some carry-over is occurring between the 35 and 75 micron particle size.

Figure C-12 presents the sand separation organic results for total PAHs, total DDTs, and PCBs measured in ug/kg. As with the inorganics, four samples were collected for bulk material chemistry, which includes a range of values and an average concentration denoted by the dark purple bar. Six separate post-processing samples were collected during the testing period for both coarse and fine grained, washed sand indicated in the graphs as CS and FS, respectively. Overall, the hydrocyclone separation process was much more efficient at removing PCB contaminants than was observed with the metals. However, PAHs and DDT showed similar results in that the CS samples were lower than the FS results indicating that some carry-over was also detected.

To evaluate the effectiveness of adding a washing process after the hydrocyclones as a way to increase the efficiency of removing the finer particle containing residual contamination, a series of tests were conducted using two approaches. The first approach consisted of simply adding the post processed sand (both CS and FS) to sample jars containing site water and shaking it

vigourously to create a slurry. The material was then allowed to settle and the fine grained material was decanted and discarded. This process was repeated two more times and the remaining “washed” sand was submitted for testing (labeled as “Manual”). The second approach consisted of using a garden hose with a spray nozzle to pump site water over the material (both CS and FS) as it exited the hydrocyclone to help strip fine-grained particles that may have carried over in the process. These post processed samples were also submitted for chemical analyses and labeled as “Mechanical”.

Figure C-13 presents the results of the washing experiments. The results for six metals (mercury, copper, lead, cadmium, zinc, and nickel) are presented for both manual and mechanical washing. Bulk sediment concentrations represent test material before entering the hydrocyclones. For the washed material, the blue bars represent the material concentrations after the hydrocyclones but prior to washing and the light purple bars present the post-washing concentrations. As a general trend, both washing approaches resulted in decreased metal concentrations. Overall, mercury had the highest concentration reduction on a percentage basis and the manual washing approach appeared to show a greater reduction than the mechanical washing approach.

Figure C-14 presents the washing experiment results for total PAHs, total DDT and PCBs. As expected, total PAH, total DDT, and total PCBs concentrations were highest in bulk sediment concentrations, followed by the pre and then the post washing tests for the CS and FS samples. One sample from Mechanical FS exceeded 2000 ug/kg for total PAHs. Overall, PAHs and DDTs showed greater concentration reductions than were observed with the metals. Total PCBs were eliminated after passing through only the hydrocyclones so the washing tests were not needed.

Figure C-15 presents the Total Organic Carbon (TOC) results for the washing experiment. TOC is measured in percentage with nine samples including bulk weight (bulk), coarse sand (7-11 CS, 7-12-CS), coarse sand washed (7-11-CSW, 7-12-CSW), fine sand (7-11-FS, 7-12-FS), fine sand washed (7-11-FSW, 7-12-FSW).

The bulk weight had the highest concentration of the nine samples taken at just above 1.5 percent. The other eight samples had TOC concentrations of less than 0.5 percent.

Chemical concentrations for the sludge material (fines output from the hydrocyclones), after settling in the Baker tanks, are presented in Figure C-16. Four metals (Copper, Lead, Zinc, and Nickel), total PAH, DDTs and PCBs are presented for the bulk, CS, FS, and sludge material for sediments processed on the same day. As expected, sludge samples contained the highest chemical concentrations for both the metals and organics.

To further investigate the results observed during the washing experiments (Figures C-13 through C-15), a subsequent study was conducted to isolate the specific sediment fraction containing the majority of the contaminants. In this test, bulk sediment from the LARE, washed coarse sand from the 10" hydrocyclone and washed fine sand from the 4" hydrocyclones were separated in the laboratory using sieves into three categories (2000-63 μ , 63-10 μ , and <10 μ) and tested for chemical concentrations. Results, presented in Figures C-17 and C-18, clearly show that the majority of sediment contaminants are found in the <10 μ clay fraction. Therefore, the addition of washing processes to eliminate this size fraction from the carry-over material would be very beneficial to the overall treatment design.

Process Water Test Results

Process water used for the pilot study was initially collected via submerged pipe from the LARE next to the work barge housing the hydrocyclones. Water was pumped into the slurry tank and combined with the sediment to create a mixture containing approximately 10% solids before transferring it into the scalper unit. After sand removal, the resulting fine-grained sediment slurry was re-circulated back to the mixing tank and reused to mix with additional bulk sediments. This process was repeated until the water became super-saturated with fines at which time it was pumped into settling tanks and new seawater was collected to restart the process. Each batch of water was then allowed to settle until the overlying water was clear before returning it to the LARE (decant only). The settled solids were collected and disposed of at the Port of Los Angeles.

Prior to discharge, the settled water was tested for suspended solids and total recoverable chemical concentrations (metals, PAHs, pesticides and PCBs). Test results were then compared to initial process water chemistry concentrations as well as EPA Ambient Water Quality Criteria (Table C-1) to evaluate for potential water quality impacts and need for further treatment. Analytical results are presented for two test scenarios. One test scenario included collecting the

water immediately after leaving the hydrocyclone (i.e., no settling), and again after filtering through 1 and 50 μ bag filters. The second test included allowing the same water as used in test #1 to settle for approximately 15 hours, collecting the overlying water and then passing it through 1 and 50 μ bag filters to simulate additional treatment.

Test results showed that the unsettled water (discharge slurry from the hydrocyclones) contained very high particulate loads and chemical concentrations. The bag filters were quickly overloaded and considerable chemicals of concern were able to pass through the filter media and render them ineffective. Allowing the water to settle overnight, however, resulted in a dramatic improvement in water quality. Both suspended solids and chemical concentrations were much lower in the unfiltered water, but still 2 to 3 times higher than the initial water collected from the LARE. Passing the water through the bag filters also resulted in additional improvements. The water passing through the 1 μ filter produced water very similar to the site water and significantly below EPA's discharge criteria for instantaneous releases.

These results suggest that simply allowing the water to settle before discharge may be sufficient for water quality compliance. If it is not, adding some form of mechanical filtration system like adding bag filters can be a very effective solution.

Production Rates and Costs:

Production rates for the field pilot study were kept at a minimum because the primary goal for the study was to determine treatment effectiveness and potential for use in a regional treatment facility. Although the Tri-Flo International equipment can include the use of two 10" hydrocyclones, only one was tested for the pilot study. Table C-2 presents a summary of the production rates observed for the pilot study vs. that which the equipment is conservatively capable of producing.

Field pilot study costs were not representative of future test scenarios for this technology because of the following:

- Not all the equipment that was obtained was needed resulting in significant excess mobilization and equipment rental costs; and

- Conducting the project on barges required significant additional effort mobilizing the equipment and transferring the bulk sediment from a storage barge to a work barge (required the use of a derrick barge for the entire study);

Areas for Improvement:

During the hydrocyclone field pilot study, several problem areas were identified for future investigation and/or modification. Most significantly was the inefficiency of the system to handle large debris and trash, and at creating slurry of suitable solids content. The approach used in the pilot study was to dump the bulk sediment into a large mixing tank containing a high velocity re-circulating pump. On top of the tank was a mesh screen to catch the large debris prior to entering the mix tank. The difficulty with this approach was that the bulk sediment did not flow through the screen and had to be manually washed into the slurry tank. A vibrating concrete mixer was later added to provide a vibration source to further help the process. The net result was that slurry solids concentrations were below the target level for optimal use of the hydrocyclone. Future uses of this equipment should include either a hydraulically dredged source and/or a macerator system to grind up the debris as it is mixed with the dilution water.

An additional area for improvement is the inclusion of a wash system to the output screens for the hydrocyclones to further rinse fine-grained material that is not separated in the cones. The material leaving the 10" hydrocyclone still contained between 4 and 14% silts and clays carried over by the system. To provide an additional washing step, the use of seawater spray rinsing was evaluated and resulted in nearly complete removal of the silts and clays, and subsequently lower contaminant levels (Figures C-13 and C-14).

Table C-2
Pilot Study Equipment Comparison to Equipment Capacity

LARE Field Pilot Study	Tri-Flo Equipment Capacity
1-10" hydrocyclone and 8-4" hydrocyclones/unit	2-10" hydrocyclones and 8-4" hydrocyclones/unit
500 gal/min	1000 gal/min
~10% solids	~15% solids
6 yards/hour (bulk)	22-30 yards/hour (bulk)
20 hrs/day = 120 yards/day	20 hrs/day = 440-600 yards/day

Table C-3
Field Pilot Study – Sediment Sample Log

Sample Date	Sample ID	Sample Description
7-8-05	7-8-D-1	Debris sample from #30/40 mesh scalper screen.
7-8-05	7-8-CS-1	75 μ course sand, collected at 1300 hrs
7-8-05	7-8-FS-1	35 μ fine sand, collected at 1300 hrs
7-8-05	7-8-CS-2	75 μ course sand, collected at 1500 hrs
7-8-05	7-8-FS-2	35 μ fine sand, collected at 1500 hrs
<i>Production Note – Changed scalper screen to larger #20 mesh due to high sand content in debris</i>		
7-9-05	7-9-sludge-1	Sludge collected from bottom of settling tank
7-9-05	7-9-CS-1	75 μ course sand, collected at 1300 hrs
7-9-05	7-9-FS-1	35 μ fine sand, collected at 1300 hrs
7-11-05	7-11-CS-1	75 μ course sand, collected at 1300 hrs
7-11-05	7-11-FS-1	35 μ fine sand, collected at 1300 hrs
7-11-05	7-11-CSW-1	75 μ course sand, collected at 1300 hrs, hand washed*
7-11-05	7-11-FSW-1	35 μ fine sand, collected at 1300 hrs, hand washed*
7-12-05	7-12-CS-1	75 μ course sand, collected at 1300 hrs
7-12-05	7-12-FS-1	35 μ fine sand, collected at 1300 hrs
7-12-05	7-12-CSW-1	75 μ course sand, collected at 1300 hrs, spray washed**
7-12-05	7-12-FSW-1	35 μ fine sand, collected at 1300 hrs, spray washed**
7-12-05	7-12-solids-1	Slurry collected at 1400 hrs prior to scalper
7-12-05	7-12-solids-2	Slurry collected at 1430 hrs with attempt at higher solids
7-13-05	7-13-CS-1	75 μ course sand, collected at 1300 hrs
7-13-05	7-13-FS-1	35 μ fine sand, collected at 1300 hrs

* Hand washing consisted of filling the sample jar with site water and sand, shaking it vigorously for 10 seconds, and then decanting the suspended material in the overlying water. This process was repeated 2 additional times and then a sample was collected.

** Spray washing consisted of adding a garden hose with spray nozzle over the shaker screen leaving the 10" hydrocyclone and rinsing the material as it passes by.

Table C-4
Field Pilot Study – Process Water Sample Log

Sample Date	Sample ID	Sample Description
7-8-05	7-8-LARE-RAW	Raw site water collected from the LARE at 1300 hrs
7-8-05	7-8-WBF1-1	Unsettled slurry water after 1 μ bag filter at 1400 hrs
7-8-05	7-8-WBF1-50	Unsettled slurry water after 50 μ bag filter at 1400 hrs
7-8-05	7-8-Slurry-1	Unsettled slurry water at 1400 hrs.
7-9-05	7-9-WBF1-1	Settled slurry water after 1 μ bag filter at 1200 hrs
7-9-05	7-9-WBF1-50	Settled slurry water after 50 μ bag filter at 1200 hrs
7-9-05	7-9-Slurry-1	Settled slurry water after 15hrs – no filtration – collected at 1200 hrs

APPENDIX D
SAND SEPARATION LAB AND FIELD PILOT STUDY ANALYTICAL
DATA

APPENDIX D

Table of Contents

Texas Lab Pilot Study (Appendix B)

- Raw Data Packet 1 Trace Metals, Chlorinated Pesticides, Arcolor PCB, PCB Congeners, Polynuclear Aromatic Hydrocarbon data for Sample IDs Bulk Rhine, Rhine Sand, Rhine Cake, Rhine Decant and QAQC collected on February 24, 2005.
- Raw Data Packet 10 Total Organic Carbon data for Sample ID Rhine Decant collected on February 24, 2005
- Raw Data Packet 11 Grain Size data for Sample IDs Bulk Rhine, Rhine Sand, and Rhine Cake, Collected on March 4, 2005

LARE Field Pilot Study (Appendix C)

- Raw Data Packet 3 Trace Metals, Chlorinated Pesticides, Arcolor PCB, PCB Congeners, Polynuclear Aromatic Hydrocarbon data for Sample IDs LARE Sand and Fines collected on June 23, 2005
- Raw Data Packet 5 Trace Metals, Chlorinated Pesticides, Arcolor PCB, PCB Congeners, Polynuclear Aromatic Hydrocarbon data for Sample IDs 7-9-Slurry, 7-9-WBF 1-1, 7-9-WBF 1-50, QAQC, collected on July 9, 2005
- Raw Data Packet 2 Grain Size Data for Sample ID's P2563b collected on July 1, 2005
- Raw Data Packet 4 Trace Metals, Chlorinated Pesticides, Arcolor PCB, PCB Congeners, Polynuclear Aromatic Hydrocarbon data for Sample IDs 7-8-LARE RAW, 7-8-WBF1-1, 7-8-WBF1-50, 7-8-Slurry-1, QAQC, 7-8-D-1, 7-8-CS-1, 7-8-FS-1, collected on July 8, 2005

- Raw Data Packet 6 Trace Metals, Chlorinated Pesticides, Arcolor PCB, PCB Congeners, Polynuclear Aromatic Hydrocarbon data for Sample IDs 7-9- FS-1, 7-9- CS-1, 7-9-FS-2, 7-9-CS-2, collected on July 9, 2005
- Raw Data Packet 7 Total Organic results for Sample IDs 7-11-FS-1, 7-11-CS-1, 7-11-FSW-1, 7-11-CSW-1, 7-12-FS-1, 7-12-CS-1, 7-12-FSW-1, and 7-12-CSW-1
- Raw Data Packet 8 Trace Metals, Chlorinated Pesticides, Arcolor PCB, PCB Congeners, Polynuclear Aromatic Hydrocarbon data 7-11-FS-1, 7-11-CS-1, 7-11-FSW-1, 7-11-CSW-1, 7-12-FS-1, 7-12-CS-1, 7-12-FSW-1, 7-12-CSW-1, collected on July 11, 2005
- Raw Data Packet 9 Trace Metals, Chlorinated Pesticides, Arcolor PCB, PCB Congeners, Polynuclear Aromatic Hydrocarbon data for Sample IDs 7-13-CS-1 and 7-13-FS-1, collected on July 13, 2005

Raw Data Packet 1

**Trace Metals, Chlorinated Pesticides, Arcolor PCB, PCB Congeners,
Polynuclear Aromatic Hydrocarbon data for Sample IDs Bulk Rhine,
Rhine Sand, Rhine Cake, Rhine Decant and QAQC collected on
February 24, 2005**

Re: CRG Project ID: P2563
Anchor Project: Tri-Flo Bench Test

ATTN: Steve Cappellino

CRG Laboratories is pleased to provide you with the enclosed analytical data report for your Tri-Flo Bench Test project. According to the chain-of-custody, 5 samples were received intact and cool at CRG on February 25, 2005. Per your instructions, the samples were processed and analyzed for:

- Trace Metals By ICPMS Using EPA Method 6020 & 1640
- Chlorinated Pesticides By GCMS Using EPA Method 8270 & 625
- Polychlorinated Biphenyls and Aroclor (PCBs) By GCMS Using EPA Method 8270 & 625
- Polynuclear Aromatic Hydrocarbons (PAHs) By GCMS Using EPA Method 8270 & 625
- Percent Solids Using EPA 160.3

Grain Size and TOC/DOC were subcontracted to other laboratories, results are included.

Please don't hesitate to call if you have any questions and thank you very much for using our laboratory for your analytical needs.

Regards,
Misty B. Mercier
Project Manager

Client Reference: P2563

Dear Client:

Enclosed is an analytical report for the above-referenced project. The samples included in this report were received 2/28/2005 and analyzed in accordance with the attached chain-of-custody.

Unless otherwise noted, all analytical testing was accomplished in accordance with the guidelines established in our Quality Assurance Program Manual, applicable standard operating procedures, and other related documentation. The original report of any subcontracted analysis is provided herein, and follows the standard Calscience data package. The results in this analytical report are limited to the samples tested and any reproduction thereof must be made in its entirety.

If you have any questions regarding this report, please do not hesitate to contact the undersigned.

Sincerely,

A handwritten signature in black ink, appearing to read "Jason Torres".

Glossary of Terms and Qualifiers

Work Order Number: 05-02-1543

<u>Qualifier</u>	<u>Definition</u>
*	See applicable analysis comment.
1	Surrogate compound recovery was out of control due to a required sample dilution, therefore, the sample data was reported without further clarification.
2	Surrogate compound recovery was out of control due to matrix interference. The associated method blank surrogate spike compound was in control and, therefore, the sample data was reported without further clarification.
3	Recovery of the Matrix Spike or Matrix Spike Duplicate compound was out of control due to matrix interference. The associated LCS and/or LCSD was in control and, therefore, the sample data was reported without further clarification.
4	The MS/MSD RPD was out of control due to matrix interference. The LCS/LCSD RPD was in control and, therefore, the sample data was reported without further clarification.
5	The PDS/PDSD associated with this batch of samples was out of control due to a matrix interference effect. The associated batch LCS/LCSD was in control and, hence, the associated sample data was reported with no further corrective action required.
A	Result is the average of all dilutions, as defined by the method.
B	Analyte was present in the associated method blank.
C	Analyte presence was not confirmed on primary column.
E	Concentration exceeds the calibration range.
H	Sample received and/or analyzed past the recommended holding time.
J	Analyte was detected at a concentration below the reporting limit and above the laboratory method detection limit. Reported value is estimated.
N	Nontarget Analyte.
ND	Parameter not detected at the indicated reporting limit.
Q	Spike recovery and RPD control limits do not apply resulting from the parameter concentration in the sample exceeding the spike concentration by a factor of four or greater.
U	Undetected at the laboratory method detection limit.
X	% Recovery and/or RPD out-of-range.
Z	Analyte presence was not confirmed by second column or GC/MS analysis.

P2563

Target Sample Summary

Sample	Matrix	Metals	PAHs	PCBs	Pesticides	G.S.	% Solids	TOC	DOC
Bulk Rhine	Sediment	x	x	x	x	x	x	x	
Rhine Diluted	Slurry						x		
Rhine Sand	Sediment	x	x	x	x	x	x	x	
Rhine Cake	Slurry	x	x	x	x	x	x	x	
Rhine Decant	Water	x	x	x	x			x	x

Bottle Count:

- Bulk Rhine – one 500ml glass jar
- Rhine Diluted – one 500ml glass jar (analyze as slurry) ~ 90% H₂O
- Rhine Sand - one 500ml glass jar
- Rhine Cake – two 500ml glass jars (need to be filtered and then the solids only analyzed)
- Rhine Decant – two 1 L amber glass bottles, one 250 ml HDPE bottle for metals, one 250ml HDOE bottle for TOC, one 250ml glass bottle for DOC

Project Notes:

1. Started with approximately 6-8 gallons of Rhine Channel sediment of unknown moisture content.
2. Diluted with 176 gallons of artificial seawater prepared using Instant Ocean salts to a salinity of 28-30 ppt.

Re: CRG Project ID: P2563b
 Anchor Project: LARE Sediment Separation

ATTN: Steve Cappellino

CRG Laboratories is pleased to provide you with the enclosed analytical data report for your LARE Sediment Separation project. According to the chain-of-custody, 2 samples were received intact and cool at CRG on June 23, 2005. Per your instructions, the samples were processed and analyzed for:

- Trace Metals By ICPMS Using EPA Method 6020
- Chlorinated Pesticides By GCMS Using EPA Method 8270
- Polychlorinated Biphenyls and Aroclor (PCBs) By GCMS Using EPA Method 8270
- Polynuclear Aromatic Hydrocarbons (PAHs) By GCMS Using EPA Method 8270

Grain Size analysis was subcontracted to another laboratory, results are included.

Please don't hesitate to call if you have any questions and thank you very much for using our laboratory for your analytical needs.

Regards,
Misty B. Mercier
Project Manager

Re: CRG Project ID: P2563c
 Anchor Project: LARE Sediment Separation

ATTN: Steve Cappellino

CRG Laboratories is pleased to provide you with the enclosed analytical data report for your LARE Sediment Separation project. According to the chain-of-custody, 3 sediment and 4 seawater samples were received intact and cool at CRG on July 8, 2005. Per your instructions, the samples were processed and analyzed for:

- Trace Metals By ICPMS Using EPA Method 1640, 200.8, 6020
- Chlorinated Pesticides By GCMS Using EPA Method 625 & 8270
- Polychlorinated Biphenyls and Aroclor (PCBs) By GCMS Using EPA Method 625 & 8270
- Polynuclear Aromatic Hydrocarbons (PAHs) By GCMS Using EPA Method 625 & 8270

Grain Size analysis was subcontracted to another laboratory, results are included.

Please don't hesitate to call if you have any questions and thank you very much for using our laboratory for your analytical needs.

Regards,
Misty B. Mercier
Project Manager

Subject: RE: LARE samples

sorry - too much sun that day - just PAHs.

Subject: LARE samples

Hi Steve,

just to confirm the coc that accompanied ~~our~~ samples last Fri, to us SVOC = PAHs + BaseNeutral (including Phthalates) and Acid Extractable compounds or do you want just PAHs.

thanks,
misty

Re: CRG Project ID: P2563d
Anchor Project: LARE

ATTN: Steve Cappellino

CRG Laboratories is pleased to provide you with the enclosed analytical data report for your LARE project. According to the chain-of-custody, 3 seawater samples were received intact and cool at CRG on July 11, 2005. Per your instructions, the samples were processed and analyzed for:

- Trace Metals By ICPMS Using EPA Method 1640
- Chlorinated Pesticides By GCMS Using EPA Method 625
- Polychlorinated Biphenyls and Aroclor (PCBs) By GCMS Using EPA Method 625
- Polynuclear Aromatic Hydrocarbons (PAHs) By GCMS Using EPA Method 625
- Total Suspended Solids Using SM 2540 D

Please don't hesitate to call if you have any questions and thank you very much for using our laboratory for your analytical needs.

Regards,
Misty B. Mercier
Project Manager

Re: CRG Project ID: P2563e
Anchor Project: LARE Sediment Separation

ATTN: Steve Cappellino

CRG Laboratories is pleased to provide you with the enclosed analytical data report for your LARE Sediment Separation project. According to the chain-of-custody, 5 samples were received intact and cool at CRG on July 11, 2005. Per your instructions, the samples were processed and analyzed for:

- Trace Metals By ICPMS Using EPA Method 6020
- Chlorinated Pesticides By GCMS Using EPA Method 8270
- Polychlorinated Biphenyls and Aroclor (PCBs) By GCMS Using EPA Method 8270
- Polynuclear Aromatic Hydrocarbons (PAHs) By GCMS Using EPA Method 8270

Grain Size analysis was subcontracted to another laboratory, results are included.

Please don't hesitate to call if you have any questions and thank you very much for using our laboratory for your analytical needs.

Regards,
Misty B. Mercier
Project Manager

Re: CRG Project ID: P2563f
 Anchor Project: LARE

ATTN: Steve Cappellino

CRG Laboratories is pleased to provide you with the enclosed analytical data report for your LARE project. According to the chain-of-custody, 8 sediments and 2 seawater samples were received intact and cool at CRG on July 12, 2005. Per your instructions, the samples were processed and analyzed for:

- Trace Metals By ICPMS Using EPA Method 6020
- Chlorinated Pesticides By GCMS Using EPA Method 8270
- Polychlorinated Biphenyls and Aroclor (PCBs) By GCMS Using EPA Method 8270
- Polynuclear Aromatic Hydrocarbons (PAHs) By GCMS Using EPA Method 8270
- Total Solids Using SM 2540 D

Grain Size and TOC were subcontracted to other laboratories, results will follow.

Please don't hesitate to call if you have any questions and thank you very much for using our laboratory for your analytical needs.

Regards,
Misty B. Mercier
Project Manager

Re: CRG Project ID: P2563g
Anchor Project: LARE Sediment Separation

ATTN: Steve Cappellino

CRG Laboratories is pleased to provide you with the enclosed analytical data report for your LARE Sediment Separation project. According to the chain-of-custody, 2 samples were received intact at CRG on July 13, 2005. Per your instructions, the samples were processed and analyzed for:

- Trace Metals By ICPMS Using EPA Method 6020
- Chlorinated Pesticides By GCMS Using EPA Method 8270
- Polychlorinated Biphenyls and Aroclor (PCBs) By GCMS Using EPA Method 8270
- Polynuclear Aromatic Hydrocarbons (PAHs) By GCMS Using EPA Method 8270

Grain Size analysis was subcontracted to another laboratory, results are included.

Please don't hesitate to call if you have any questions and thank you very much for using our laboratory for your analytical needs.

Regards,
Misty B. Mercier
Project Manager

Subject: RE: P2563d rush metals

OK - thanks. Jim dropped off the last two samples that we will have coming to you for this project (think he was there an hour ago). When the dust settles (maybe late tomorrow or Friday) can you have Mark send me a total estimate of the costs for what we actually had completed? I need to get it into the Corps so that they can modify my contract.

Thanks,
S

Hi Steve,

I checked with the metals & organics lab...we can do 1day TAT for the metals and 2day TAT for the organics.

thanks,
misty

Dear Client:

Enclosed is an analytical report for the above-referenced project. The samples included in this report were received 2/28/2005 and analyzed in accordance with the attached chain-of-custody.

Unless otherwise noted, all analytical testing was accomplished in accordance with the guidelines established in our Quality Assurance Program Manual, applicable standard operating procedures, and other related documentation. The original report of any subcontracted analysis is provided herein, and follows the standard Calscience data package. The results in this analytical report are limited to the samples tested and any reproduction thereof must be made in its entirety.

If you have any questions regarding this report, please do not hesitate to contact the undersigned.

Sincerely,

A handwritten signature in black ink, appearing to read "Jason Torres".

Glossary of Terms and Qualifiers

Work Order Number: 05-02-1543

<u>Qualifier</u>	<u>Definition</u>
*	See applicable analysis comment.
1	Surrogate compound recovery was out of control due to a required sample dilution, therefore, the sample data was reported without further clarification.
2	Surrogate compound recovery was out of control due to matrix interference. The associated method blank surrogate spike compound was in control and, therefore, the sample data was reported without further clarification.
3	Recovery of the Matrix Spike or Matrix Spike Duplicate compound was out of control due to matrix interference. The associated LCS and/or LCSD was in control and, therefore, the sample data was reported without further clarification.
4	The MS/MSD RPD was out of control due to matrix interference. The LCS/LCSD RPD was in control and, therefore, the sample data was reported without further clarification.
5	The PDS/PDSD associated with this batch of samples was out of control due to a matrix interference effect. The associated batch LCS/LCSD was in control and, hence, the associated sample data was reported with no further corrective action required.
A	Result is the average of all dilutions, as defined by the method.
B	Analyte was present in the associated method blank.
C	Analyte presence was not confirmed on primary column.
E	Concentration exceeds the calibration range.
H	Sample received and/or analyzed past the recommended holding time.
J	Analyte was detected at a concentration below the reporting limit and above the laboratory method detection limit. Reported value is estimated.
N	Nontarget Analyte.
ND	Parameter not detected at the indicated reporting limit.
Q	Spike recovery and RPD control limits do not apply resulting from the parameter concentration in the sample exceeding the spike concentration by a factor of four or greater.
U	Undetected at the laboratory method detection limit.
X	% Recovery and/or RPD out-of-range.
Z	Analyte presence was not confirmed by second column or GC/MS analysis.
